Scientific arguments coming from astronomical and geological observations and theoretical developments concerning heat propagation, thermodynamics, geodesy, and mechanics led to the proposal that the Earth is stratified, with a silicate mantle and an iron core. But the specification of core properties is mostly derived from seismological observations. Combined with mineral physics, they have allowed us to obtain the present picture of the Earth, made of a silicate mantle, an iron liquid core, and a solid iron inner core, with a radius of 3480 km (0.55 ×Earth radius) for the CMB and a radius of 1220 km (0.19 ×Earth radius) for the ICB.

1.23.2.1 Indirect Evidences for the Existence of a Core and Historical Controversies

The fascination for the Earth's interior is present in the literature since the antiquities (see historical aspects in Brush, 1980; Bolt, 1982; Deparis and Legros, 2002). During the nineteenth century, it is generally accepted that the Earth has been fluid at its origin. This idea resulted mostly from the observation of the Earth flattening, an equilibrium figure supposed to be acquired during fluid stage, and from the identification of plutonic rocks. The question was raised of whether the Earth is still fluid in its interior, or solid as a result of its complete cooling, or partly solid. The geothermal gradient measured at the surface (about 30 °C km^{-1}) predicts a melting of the Earth silicates at about 80–100 km depth, an idea reinforced by the fluid lavas rejected by volcanoes. An argument against this model is given by Ampère (1775–1836), who noted that such a structure would not be able to support the high stresses induced by the lunar tides on the thin solid envelope. On the other hand, Poisson (1781–1840) noted that the melting temperature of rocks increases with pressure, opening the possibility of a completely solid Earth.

Two discoveries have allowed us to reconcile a solid Earth model with the high geothermal gradient: first, the idea that the internal heat is eliminated not only by conduction but also (and mostly) by convection and, second, the discovery of radioactivity as a source of internal heat, in addition to the initial heat. These two discoveries explain the impossibility of extrapolating the upper crust geothermal gradient downward. On the other hand, the comparison of the precession and nutations of the Earth observed from astronomy with those computed for different structures led Hopkins (1793–1866) to propose a solid envelope of at least 1000 km thickness, the fluid center being thus much too deep for being the feeding region of the volcanoes. More refined computations by Kelvin (1824–1907) gave a 2000–2500 km thickness for the solid envelope.

The mean density of the Earth, 5.52×10^3 kg m^{-3}, is much higher than that of the rocks (about 2.6×10^3 kg m^{-3} for granite), even at the temperature and pressure conditions present at 2500 km depth. Its moment of inertia, $I = 0.33\ Ma^2$, where M is the mass of the Earth and a its radius, is smaller than that of a homogeneous sphere ($I = 0.40\ Ma^2$), implying high densities at depth, thus a chemical differentiation. Geochemical arguments, in particular cosmic abundances and the existence of both silicate and iron meteorites, led to propose an iron core. Stony-iron meteorites such as pallasites may represent the CMB. At the end of the nineteenth century, a model with a silicate mantle above an iron core was widely accepted (e.g., Wiechert, 1896).

The effective detection of the core is, however, attached to seismology. In 1889, the first recording of a remote earthquake opened the possibility of sampling deep Earth structure with teleseismic data. This discovery stimulated the deployment of worldwide observatories and the international organization of seismology (see **Chapter 1.01**).

1.23.2.2 The Seismological Detection of the Liquid Core and Inner Core

Most of the teleseismic records exhibit two clear arrivals, a primary, compressional phase (P), and a secondary, shear phase (S). Oldham (1906) noted that the propagation time of the S-wave as a function of distance was delayed by about 10 min for angular distances larger than 130°. He ascribed this delay to the propagation through a core in which the velocity is smaller than in the mantle, due to a change in physical properties. Although the observed late phase was not S, but SS (an S phase reflected once beneath the surface), this observation led to consider that Oldham is the discoverer of the core. Gutenberg (1913) determined the depth of the CMB at 2900 km, a value that has not significantly changed later. The fluidity of the core was confirmed by Jeffreys (1926) thanks to the evaluation of the mean Earth rigidity deduced from Earth tides, which is lower than the mantle rigidity deduced from seismic wave propagation. The nature of this core, mostly made of fluid iron, was established by Birch (1952, 1964), a pioneer in high-pressure physics, who demonstrated that a silicate at pressure and temperature similar to core conditions could not reach the inferred mass density of about 10^4 kg m^{-3}.

The discovery of the inner core is due to Lehmann (1936), who detected a seismic phase arrival at a distance where no P-phase is supposed to arrive, in a distance range (about 110–140°) called the shadow zone of the core (**Figure 1(a)**). She

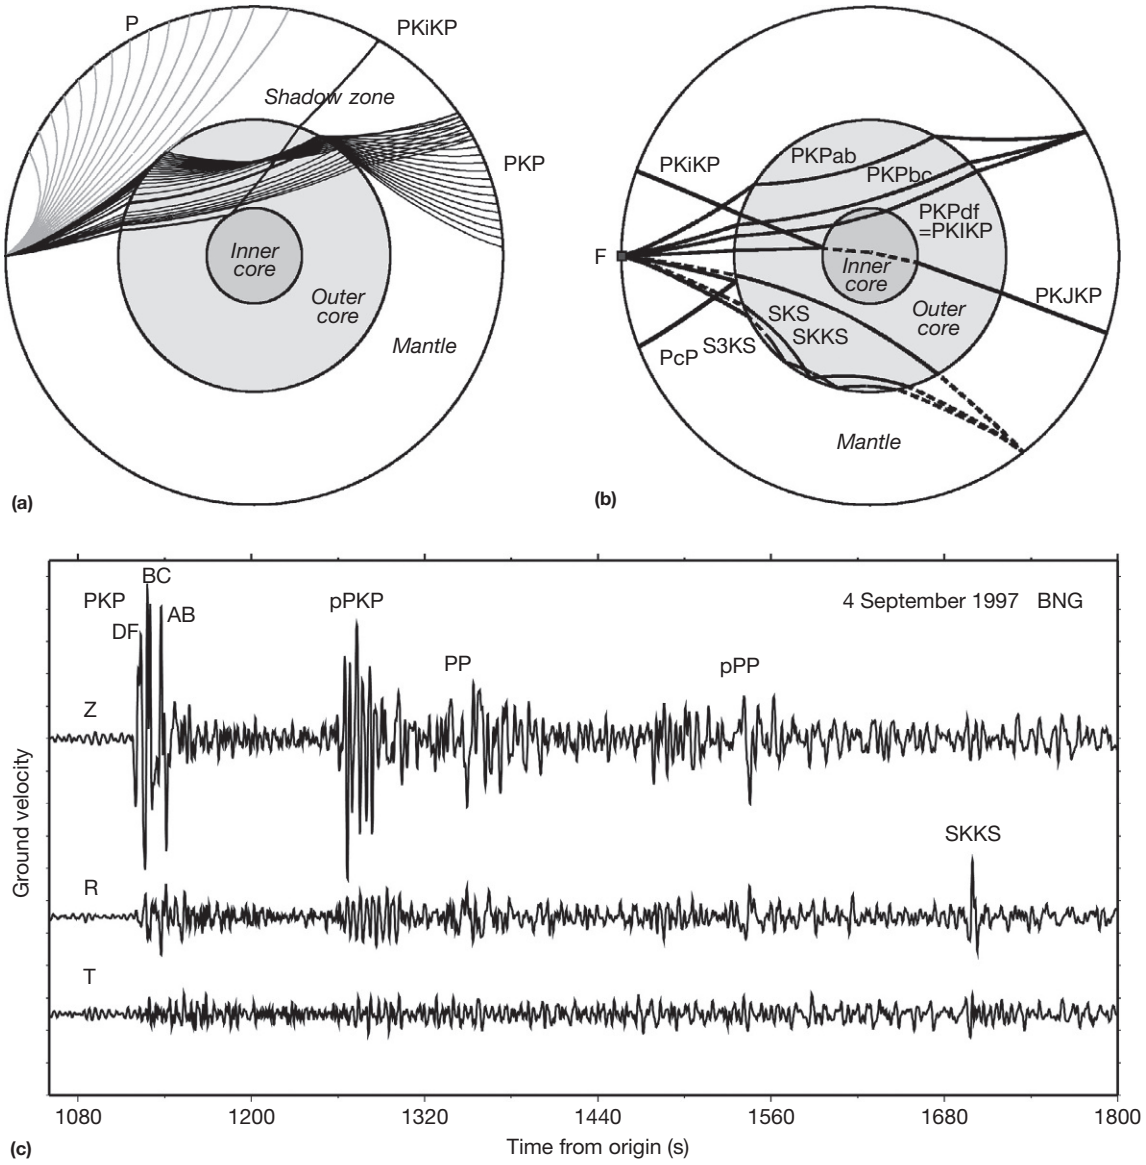

Figure 1 (a) Shadow zone of the core, due to the P-wave velocity decrease from the mantle to outer core, and PKiKP ray reflected at the inner core boundary, at the origin of the discovery of the inner core. (b) Paths of the main core phases inside the Earth propagating as P-waves (full lines) or S-waves (dashed lines). (c) Example of data: the first 11 min record of the Fiji islands, 04 September 1997 event (magnitude $M_b = 6.3$, depth = 621 km), at the Geoscope broadband station BNG (Bangui, Central African Republic), at distance 151°. Three components: Z-vertical, R-radial (in the ray direction), and T-transverse. Note the three phases of PKP on the vertical component, the pPKP phases first reflected at the Earth surface, and the SKKS phase on the radial component. The other phases are mantle phases. Courtesy of E. Stutzmann.

ascribed this phase to a P-wave reflected at an unknown discontinuity at a depth of about 5000 km, the ICB. A physical argument in favor of inner core rigidity is given by Jacobs (1953), who showed that the increase with pressure (thus with depth) of the melting point of iron must result in a phase change from liquid to solid at ICB conditions. An indirect proof of the inner core rigidity is given by the periods of the free oscillations of the Earth that are excited after large earthquakes and that are sensitive to the elastic properties of the deep Earth (Dziewonski and Gilbert, 1971).

Table 1 summarizes the main physical parameters of the core. Elastic parameters are taken from two global Earth models that are widely used as reference, PREM (Dziewonski and Anderson, 1981) and ak135 (Kennett et al., 1995). The temperature is the most poorly defined parameter, as it depends on the composition of the core, which is still debated. In particular, the presence of light elements may decrease the melting temperature of iron by 500–1000 °K (Poirier and Shankland, 1993), depending on their nature and concentration.

1.23.3 Investigation Tools

Among the various tools used to infer the core structure and properties, seismology is certainly the most powerful. Seismic waves allow us to obtain very precise values of the elastic parameters; to image lateral heterogeneities in velocities, anisotropy, and attenuation; and even to seek time variations, induced, for example, by a possible inner core rotation. However, the interpretation of the images obtained by seismology relies strongly on the results of mineral physics at high pressure and high temperature. Another important information is given by the Earth's rotation, in particular nutations and length of day, which are sensitive to the Earth's shape and stratification. The analysis of the magnetic field and its temporal variations give information on the convective motions in the liquid core, which will not be considered here (see Volume 8).

1.23.3.1 Body-Wave Seismology: The Core Phases

Core studies are based on travel times and amplitudes of the different phases sampling the core (compressional waves, shear waves, and combinations of both) and increasingly on whole waveform modeling (see Chapters 1.06 and 1.07). The worldwide digital broadband stations are the main source of waveform data. For travel times, values reported in the bulletins of the International Seismological Centre (ISC) or in derived improved catalogs (EHB file; Engdahl et al., 1998) are also used. For these data, the large amount of values collected since 1964, combined with statistical analyses, compensates for the uneven quality of single values. Finally, for some phases with a very low energy, stacking of records collected at arrays is necessary.

There are three particularities of core phases:

- S-waves, which is are shear waves, do not propagate inside the liquid core. Thus, the liquid core may be investigated only through P-waves.
- The waves sampling the core also travel twice through the mantle and crust, at station side and at source side. The crust and the base of the mantle, the so-called D″ layer, are highly heterogeneous, as well as the upper mantle in most of the source regions, because of the dipping slabs associated with subduction zones. Each time it is possible, it is thus convenient to use differential travel times between neighboring phases, which partly remove the perturbing contributions of the mantle and crust and mislocation and clock errors. In particular, the phase PKP(DF), also called PKIKP, which samples the inner core, is often compared to PKP (BC), a nearby phase that has its turning point at the base of the liquid core and has nearly the same waveform. It may also be compared to PKP(AB), which is more distant, more

affected by D″ heterogeneities, which differs from PKP(DF) by a Hilbert transform (Choy and Richards, 1975), but which is the simplest reference phase at large distance. These three PKP phases form a triplication in the PKP travel time curves as a function of distance.

– Because of their long path through the Earth, core phases have large Fresnel zones inside the core. For example, a PKP(DF) wave of 2 s period samples a tube about 500 km wide at its turning point, which is quite large compared to the inner core radius of 1220 km (Calvet et al., 2006; Figure 2). Thus, PKP(DF) returns a smeared image of the inner core.

A list of the main core phases and their use for core studies are given in Table 2. Their paths inside the Earth are shown in Figure 1(b), and an example of record is shown in Figure 1(c). Some of the paths are purely P-waves, with refractions or reflections at the core boundaries (PKP, PKKP, etc.); others are a combination of S- and P-waves, such as SKS, which propagates as S-wave in the mantle, or PKJKP, which propagates as S-wave inside the inner core.

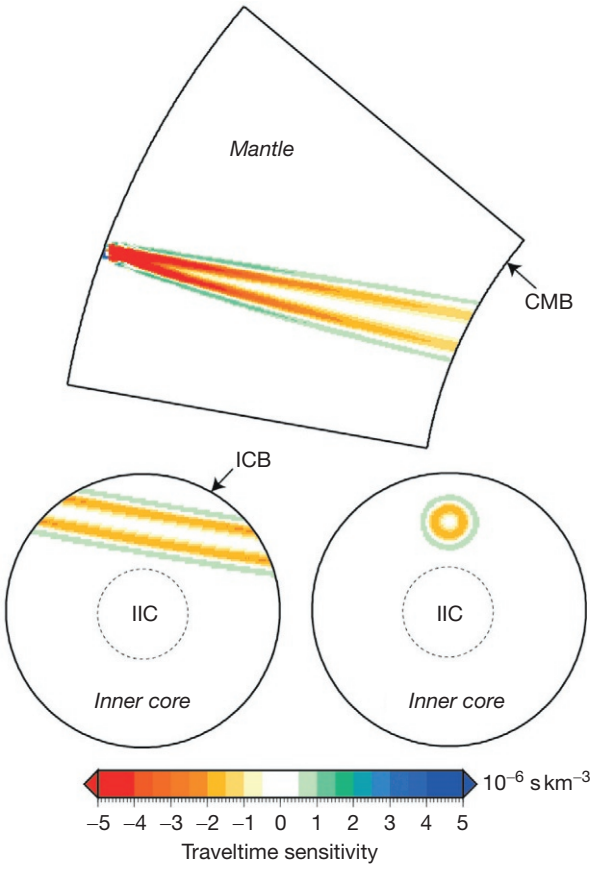

Figure 2 Travel time sensitivity kernel of PKP(DF) at 2 s period and 160° epicentral distance, giving the sensitivity of travel time to structure. (Top) Fresnel zone in the mantle along the ray. (Bottom) Fresnel zone in the inner core along the ray and perpendicular to the ray at its turning point. CMB, core–mantle boundary; ICB, inner core boundary; ICC, innermost inner core (see Section 1.23.7.2.2.3). Note the sensitivity of the PKP(DF) ray to the upper mantle structure and the large size of the Fresnel zone in the inner core, which will smear the images of small-scale heterogeneities or sharp discontinuities.

1.23.3.2 Normal Modes

The periods and amplitudes of free oscillations (or normal modes) allow us to retrieve the mean elastic parameters, density, and attenuation as a function of radius and their long wavelength heterogeneities (see Chapters 1.03 and 1.04). They avoid the problem of sparse sampling due to body waves. The splitting of the modes in multiplets gives information on the anisotropy, once the contributions of the Earth's rotation and ellipticity are corrected (e.g., Durek and Romanowicz, 1999; Dziewonski and Gilbert, 1971; Irving and Deuss, 2011a; Laske and Masters, 2003; Tromp, 1993). Modes are mostly sensitive to the even part of Earth structure. Thus, for example, a possible degree-one (hemispherical) pattern will be difficult to detect, unless mode coupling is considered (Irving et al., 2009). Moreover, only a limited number of modes have significant energy in the core, still fewer in the inner core, and mode energy decreases to zero at the Earth's center. Very large earthquakes are thus required to observe inner core-sensitive modes.

Normal modes are however crucial for core studies, as they allow us to obtain S-velocity and density (Kennett, 1998; Masters, 1979; Masters and Gubbins, 2003), which are very difficult to obtain from body waves. Moreover, they sample the low-frequency part of the spectrum, which is not accessible to body waves. Because of the fluidity of the core, only spheroidal modes are considered.

Figure 3 gives the energy in compression, shear, and density as a function of radius for various core-sensitive modes. The energy in the inner core remains small compared to that in the mantle and liquid core; it is thus necessary to combine data sensitive to different depths to reduce the influence of the mantle. The ability of modes to resolve sharp discontinuities remains however very poor.

1.23.3.3 High-Pressure Physics

High-pressure physics provides essential information for deriving the chemical, mineralogical, and textural structure of the Earth from seismic observations (see Volume 2). For example, the knowledge of the crystal structure of iron alloy is necessary for modeling seismic anisotropy in the inner core and for proposing models of core dynamics. Materials at core conditions may be explored either from laboratory experiments or from theoretical computations. Only few experiments in diamond anvil cells have reached the 360 GPa pressure present at the Earth's center. Core conditions are more easily reproduced by shock-wave experiments even if the temperature remains difficult to estimate. Computations based on first-principle molecular dynamics simulations, or ab initio computations, provide an alternative for simulating core conditions. These methods allow us to predict almost all the parameters of core materials (phase diagram of iron alloy, melting temperature, rheology, elasticity, etc.). However, the results depend on the approximations made and on the input parameters, for example, the nature and the amount of light elements included in the iron alloy.

Table 2 Main body waves sampling the core

Phase name	*Path*	*Use and peculiarities*
PKP(DF) = PKPdf = PKIKP	P propagating through the inner core	Inner core structure and anisotropy
PKP(BC) = PKPbc	P turning at the base of the liquid core	Liquid core structure Reference phase for PKP(DF) at distances 149–155°
PKP(AB) = PKPab	P turning in the middle of the liquid core	D″ structure Reference phase (poor) for PKP(DF) at large distance
PKKP = P2KP, P*n*KP	P with ($n-1$) underside reflections at CMB	Three branches (DF, BC, AB), difficult to observe CMB topography P*n*KP(BC): structure of the liquid core
PcP, ScS, PcS, ScP	P or S reflected as P or S at CMB (upperside reflection)	D″ structure CMB topography PcP: reference phase for PKiKP
PKiKP	P reflected at ICB (upperside reflection)	Topography and scatterers at ICB, density and S-velocity jump at ICB Difficult to observe at short distance
PKJKP	S through the inner core, P elsewhere	S-structure of the inner core Not directly observable
SKS, S*m*KS	S in the mantle, propagating as P in the liquid core ($m-1$) underside reflections at CMB	D″ structure Structure of the uppermost liquid core

CMB, core–mantle boundary; ICB, inner core boundary.

1.23.4 Radial Structure of the Core in Global Earth Models

The first accurate core models were derived from travel times and amplitudes of PKP and PKKP waves, from natural earthquakes, and also from nuclear explosions, which provide sources outside subduction zones. S*m*KS waves were used to constrain the upper part of the liquid core, where no PKP wave has its turning point. These models have given with a good precision the radii of the outer core and inner core and the mean velocity profiles and quality factors throughout the core (see references in Souriau and Poupinet, 1991). However, some of these models present artifacts, either because D″ heterogeneities were unmodeled or because PKP precursors, which are due to scatterers at the base of the mantle (Cleary and Haddon, 1972), were erroneously ascribed to a liquid core discontinuity (e.g., Bolt, 1962). This shows the importance of considering whole Earth inversion to obtain reliable reference core models (see **Chapter 1.01**). We will thus consider only the two global models, PREM (Dziewonski and Anderson, 1981) and ak135 (Kennett et al., 1995), which are the most commonly used (**Table 1**). Through this chapter, we will focus on the perturbations to these models inferred from the analyses of specific core phases and normal modes. Several other radial models are also convenient as reference models, for example, SP6 (Morelli and Dziewonski, 1993), IASP91 (Kennett and Engdahl, 1991), and ak135-f (Montagner and Kennett, 1995), derived from ak135 with the addition of density and

shear quality factor. They all exhibit nearly the same features and differ from each other by $<0.5\%$.

PREM (Dziewonski and Anderson, 1981; **Table 1**) was constructed using a combination of body waves and normal modes, thus allowing the authors to obtain a model not only in P- and S-velocities but also in density. The model is compatible with the mass and moment of inertia of the Earth. Moreover, a constraint on stable stratification was introduced a priori in the model before inversion, that is, the Adams–Williamson equation must be satisfied both in the liquid core and in the inner core, each of them assumed to be homogeneous. The final model does not depart significantly from this constraint, except perhaps at the very base of the liquid core. However, some models departing from this stability condition and compatible with normal mode data may also be found (Kennett, 1998).

Model ak135 (Kennett et al., 1995) is constructed from body-wave data only and is right now the best P-wave model inside the core. Its departure from PREM remains small (**Table 1**). ak135 has relatively low velocities at the top of the core but is slightly faster than PREM in the middle of the core. The main difference compared to PREM is a reduced velocity gradient at the base of the liquid core. The P-velocity jump at the ICB is larger in ak135 ($0.75\ \mathrm{km\ s^{-1}}$ instead of $0.67\ \mathrm{km\ s^{-1}}$), a value that may have implications for the percentage and nature of the light elements in the inner core. A comparison of the two models inside the core is shown in **Figure 4**.

It is important to draw attention on several particularities of the velocity profiles in the core. First, the upper part of the liquid core corresponds to a low P-velocity zone with respect to the mantle. This is at the origin of the refraction of P-wave to large distance when it encounters the CMB, giving the so-called shadow zone of the core (**Figure 1(a)** and **5**). The increase of P-velocity with depth bends the ray when its incidence angle decreases, leading to an emergence at shorter distance. This results in a triplication in the PKP travel time curve, each of the branches AB, BC, and DF sampling a different depth range in the core: AB corresponds to a turning point of the ray in the middle of the liquid core, BC at the base of the liquid core, and DF inside the inner core. The three PKP phases coexist in a small distance range between 145° and 155° (**Figure 5**). A second particularity of the velocity profile is that the S-velocity at the base of the mantle is nearly equal to the P-velocity at the top of the liquid core. Thus, the SKS wave (traveling as S in the mantle and P in the liquid core) is not strongly deflected at the CMB (**Figure 1(b)**) and may have its turning point in the uppermost liquid core. Finally, the velocity inside the inner core is nearly constant; thus, the rays are nearly straight. Note also the high Poisson's ratio in the inner core (0.44) compared to that of the mantle (0.26–0.30), which is a characteristic of metals.

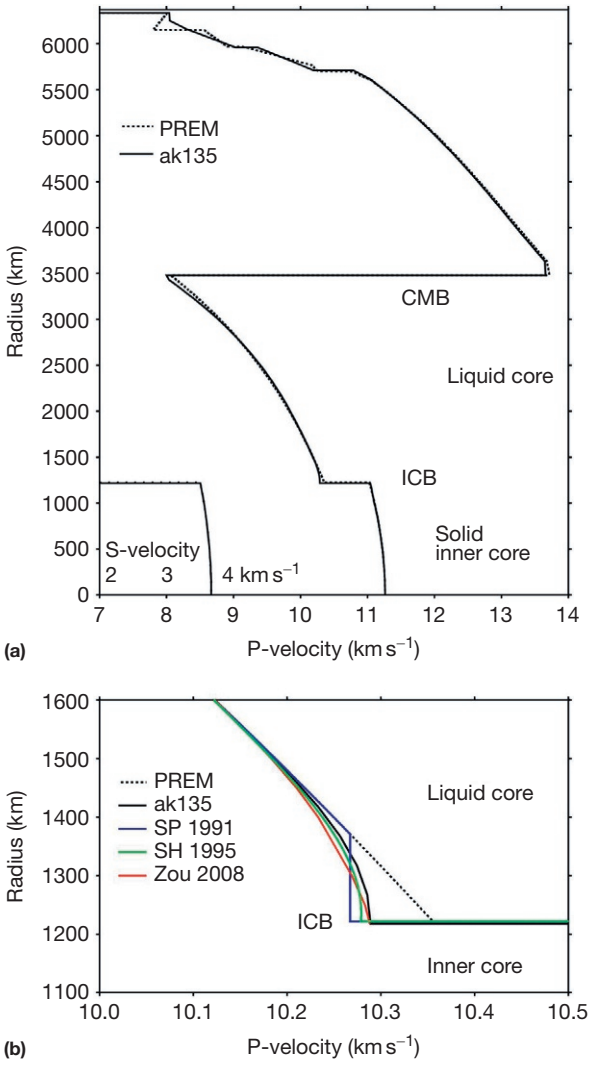

Figure 4 (a) Comparison of the P-velocities for the two global Earth models, PREM (Dziewonski and Anderson, 1981) and ak135 (Kennett et al., 1995). Also shown is the S-velocity model in the inner core (note the different scale). (b) Comparison of the velocity profiles at the base of the liquid core for PREM and ak135 and for three other specific models, Souriau and Poupinet (1991), Song and Helmberger (1995a), and Zou et al. (2008), showing the presence of a low velocity gradient.

1.23.5 The Major Discontinuities

1.23.5.1 The Core–Mantle Boundary

The CMB is the strongest discontinuity in the Earth, with a density jump of $4.3 \times 10^3\ \mathrm{kg\ m^{-3}}$, about 1.5 times larger than the density jump between the Earth's surface and atmosphere. This explains its very important role in Earth dynamics, in particular if a topography is present or if the liquid core has a high viscosity at CMB (see **Chapter 3.10**). The coupling between the core and mantle depends on amplitudes and wavelengths of the CMB topography and influences the Earth's rotation. This topography is induced by mantle dynamics, which is driven by both thermal and chemical heterogeneities (e.g., Defraigne et al., 1996; Forte et al., 1995; Greff-Lefftz and Legros, 1996; Lassak et al., 2010). Recent models predict that the amplitudes generally stay in the range ± 5 km, with a spectrum predominantly at long wavelengths (Lassak et al., 2010). The CMB is also a place where thermal, chemical, and electromagnetic interactions occur between the mantle and core (see **Chapters 7.11**, **8.08**, and **8.09**).

From the seismological point of view, the CMB appears as a first-order discontinuity. It is surrounded by the D″ layer, a

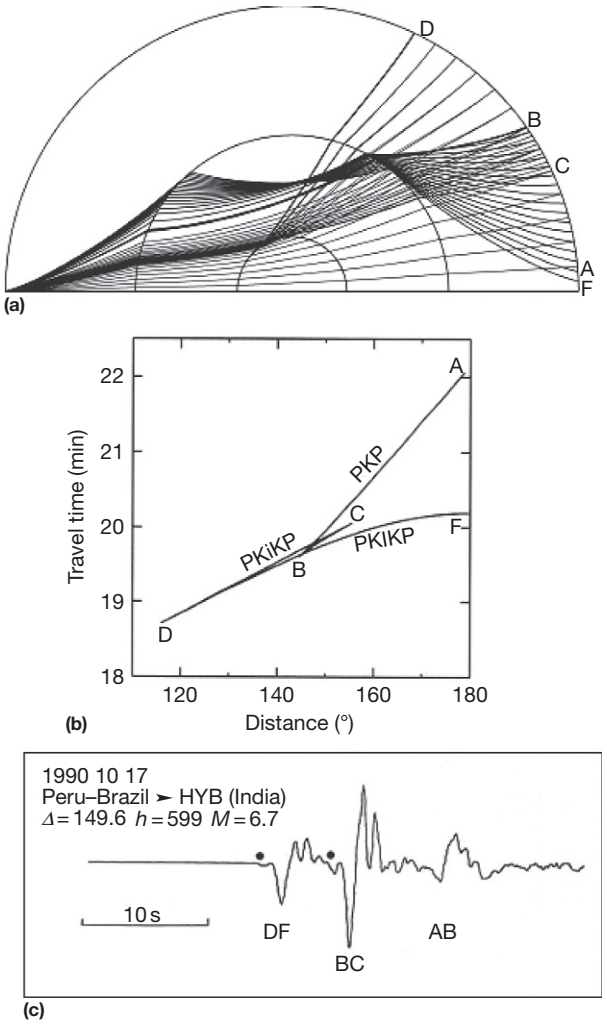

Figure 5 The PKP triplication. (a) Ray paths inside the Earth; (b) PKP travel time curve showing the triplication near 145° and the coexistence of the three PKP phases between 145° and 155°; (c) example of a deep Peru–Brazil event (depth = 599 km) recorded at the Geoscope broadband station HYB (Hyderabad, India), at distance 149.6°. Note the shape similarity between PKP(DF) and PKP(BC), whereas PKP(AB) is the Hilbert transform of PKP(BC).

very heterogeneous layer at the base of the mantle. Large low shear-wave velocity provinces corresponding to compositional heterogeneities are responsible for a strong degree two in the heterogeneity pattern of D″, but a high level of short wavelength heterogeneities is also present (see **Chapters 1.22** and **1.24**). This complex structure of D″ is the strongest difficulty to overcome for the seismological investigation of the CMB.

1.23.5.1.1 The topography of the CMB

The dynamic ellipticity may be obtained from the Earth nutations, which suggest an extra flattening (decrease of polar minus equatorial radius) of about 300–500 m, depending on the importance of the magnetic coupling at the CMB (Gwinn et al., 1986; Mathews et al., 2002). All the other results come either from modeling of mantle dynamics (see **Chapters 1.27** and **7.11**) or from seismology. Seismological results mostly rely on the analysis of travel times and amplitudes of waves reflected at the CMB or transmitted through the CMB (**Table 2**). The data are generally from bulletins. They lead to poorly consistent results, depending on the phases used and on the inverted parameters (Creager and Jordan, 1986; Morelli and Dziewonski, 1987; Rodgers and Wahr, 1993; Obayashi and Fukao, 1997; see references for other early studies in Sze and Van der Hilst, 2003). A major difficulty is the strong trade-off between D″ heterogeneities and CMB topography; it is thus important to include these two structures in the inversion of the data (e.g., Doornbos and Hilton, 1989). Even so, it is difficult to separate these two contributions. Mantle heterogeneities may also be accounted for by coupling mantle dynamics with seismological information (Soldati et al., 2012); this requires strong assumptions on the nature (thermal or chemical) of mantle heterogeneities and on mantle viscosity. Normal modes give an independent approach to the problem, but they allow us to resolve the even part of the topography only, and the trade-off with mantle heterogeneities is again strong (Koelemeijer et al., 2012; Li et al., 1991).

Studies to date propose topographic maps with amplitudes ranging from about 2 to 10 km, for wavelengths generally larger than 4000 km. They are very different from one model to the other. Normal modes give an upper limit of 5 km (Koelemeijer et al., 2012). For body-wave analyses, important biases may result from the existence of unsampled regions at the CMB surface (Pulliam and Stark, 1993). Moreover, simulations show the great difficulty to map both D″ heterogeneities and CMB topography with the presently available data (Garcia and Souriau, 2000a; Sze and Van der Hilst, 2003). A stochastic analysis of residuals of core phases shows that 95% of the CMB topography is in the range $\pm \sim 1.5$ km for characteristic lengths larger than 1200 km (Garcia and Souriau, 2000a). Similar values (± 1.75 km) are obtained in three regions around the Pacific (Koper et al., 2003). This is consistent with the most recent maps obtained at a worldwide scale (Sze and Van der Hilst, 2003), which found a peak-to-peak amplitude of about 3 km.

Short wavelength undulations responsible for wave scattering are also probably present (Rost and Revenaugh, 2004), but they must have very small amplitudes, because of the difficulty to support dynamically such heavy anomalies. They are difficult to quantify, because of the complicated signature they have in both travel times and amplitudes, as revealed by experimental and theoretical models (Emmerich, 1993; Kampfman and Müller, 1989; Menke, 1986; Rekdal and Doornbos, 1992). PcP amplitudes limit this topography to a few hundred meters in the wavelength range 2–50 km (Menke, 1986); PKKP precursors suggest topographic highs of the order of 300 m with correlation lengths of about 10 km (Earle and Shearer, 1997; Shearer et al., 1998) (see **Chapter 1.24**).

1.23.5.2 The Inner Core Boundary

This boundary is essential to understand the growing mechanism of the inner core and the thermal, chemical, and mechanical interactions between liquid and solid cores. Several models of growth are proposed, implying either a dendritic growth at the inner core surface (Bergman et al., 2003) or a slurry layer made of unconnected particles that crystallize above the ICB (Loper and Roberts, 1981; Shimizu et al., 2005). The prevailing mechanism will depend on the iron alloy present at the base of

the liquid core (Hirose et al., 2013) and on the thermodynamic conditions. Seismic data may help specify this mechanism. For example, the velocity and density contrasts at the ICB are key parameters for specifying the amount of light elements in the core and to detect partial melting at the ICB.

From the geodynamic point of view, the ICB has only a limited influence, as it corresponds to a weaker density contrast and to a smaller radius than the CMB. It has, however, an impact on the Slichter mode, a translation mode of the inner core inside the fluid whose period of about 5 h is very sensitive to the density contrast and liquid core viscosity at the ICB (Crossley et al., 1992; Rosat et al., 2006).

Seismic waveforms indicate that the ICB can generally be considered as a first-order discontinuity, <2 km thick (Cummins and Johnson, 1988a; Kawakatsu, 2006). This is consistent with thermodynamic considerations: although the uppermost inner core may incorporate fluid inclusions when it forms, it is likely to collapse under its own weight, the unconsolidated material having a thickness probably smaller than 1 km (Deguen et al., 2007).

1.23.5.2.1 The topography at ICB

The topography at ICB is certainly very weak and present at long wavelength only: first, because iron is at its melting point, thus freezing or melting will erase any topography as soon as the liquid core may transport latent heat, and, second, because the inner core has a low viscosity, probably in the range 10^{11}–10^{22} Pa s (Buffett, 1997; Deguen, 2012). Seismic waves reflected at different latitudes at the ICB show that the ellipticity is consistent with the equilibrium figure in a rotating Earth (Souriau and Souriau, 1989). An ICB topography could be induced by the gravimetric forcing of the mantle and inner core heterogeneities, with in addition the dynamic response to a possible convection inside the inner core. Mantle loading and inner core loading give each a stable topography of the order of 100 m peak to peak (Defraigne et al., 1996); thus, it could not be detected by seismological methods. However, local topographies of about 100 m to more than 10 km, with horizontal extension of a few kilometers, are reported from observations of waves reflected at the ICB by several authors (Cao et al., 2007; Dai et al., 2012; Song and Dai, 2008). If these observations are sound, they may indicate a high viscosity at the top of the inner core or the presence, at least at some places, of solid inclusions at the base of the liquid core forming a slurry boundary.

1.23.5.2.2 The density jump at ICB and its implications

At vertical incidence, the impedance contrast of a discontinuity depends primarily on its density contrast. Thus, the density jump at the ICB, $\Delta\rho_{ICB}$, may be directly obtained from the amplitude of the PKiKP waves reflected normally at the ICB. It is generally referred to the amplitude of the PcP waves reflected at the CMB, provided that the velocity and density contrasts at the CMB are known (Bolt and Qamar, 1970). As PKiKP has small amplitude at vertical incidence, stacking of several records is generally necessary to enhance the signal. Away from vertical incidence, there is a strong trade-off between density contrast, shear velocity contrast, and attenuation at the top of the inner core, as shown from waveform modeling of PKP (Cummins and Johnson, 1988b).

Density jump at the ICB ranging from 0.2 to 1.4 g cm^{-3} has been obtained from the amplitude ratios PKiKP/PcP (Figure 6) or PKiKP/P, assuming that the density contrast at the CMB has PREM's value (Cao and Romanowicz, 2004a; Koper and Dombrovskaya, 2005; Koper and Pyle, 2004; Shearer and Masters, 1990; Souriau and Souriau, 1989; Tkalčić et al., 2009). On the other hand, the data at large epicentral distances seem to require a low shear velocity jump at the ICB (2.0–2.5 km s^{-1}) compared to PREM (Cao and Romanowicz, 2004a; Koper and Pyle, 2004). These measurements are however very scattered, and this variability may reflect the sensitivity of the data to mantle structure and CMB topography, which induce wave focusing and defocusing (Leyton and Koper, 2007a). It could also reflect a variable density contrast at the CMB, which affects the reference phase PcP (Tkalčić et al., 2009), or lateral heterogeneities at the inner core surface (Krasnoshchekov et al., 2005).

Normal modes give mean values of $\Delta\rho_{ICB}$ of 0.6–1.0 g cm^{-3} (Kennett, 1998; Masters and Gubbins, 2003). Although these values correspond to a broader depth range than body waves on both ICB sides, due to mode resolution, they are globally compatible with the values obtained in the most recent body-wave studies.

The density contrast inferred from seismology is significantly too high to be explained solely by the change in volume due to a phase transition (Alfè et al., 2003). It requires chemical partitioning during crystallization, with a depletion of the inner core in light elements compared to the liquid core.

1.23.6 The Liquid Outer Core

1.23.6.1 The Main Questions Relative to Liquid Core Structure

The comparison of seismological results with high-pressure experiments and theoretical computations has shown that

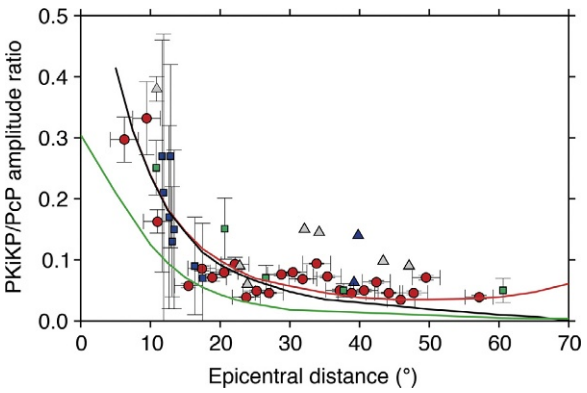

Figure 6 The amplitude ratio of the two phases PKiKP (reflected at inner core boundary ICB) and PcP (reflected at core–mantle boundary) as a function of distance, for the determination of the density contrast $\delta\rho$ and S-velocity contrast δv_S at ICB. Symbols are experimental values. Gray triangles, early results compiled by Souriau and Souriau (1989); blue triangles, Shearer and Masters (1990) (data with identified PKiKP phase); green squares, best data of Cao and Romanowicz (2004a); red dots, binned values of Koper and Pyle (2004) (horizontal bars correspond to the binning intervals); blue squares, Tkalčić et al. (2009). Curves, theoretical values; black, PREM ($\delta\rho = 0.6$ g cm^{-3}, $\delta v_S = 3.5$ km s^{-1}); green, same as PREM with $\delta\rho = 0$, showing the need for depletion in light elements during crystallization; red, same as PREM with $\delta v_S = 2.5$ km s^{-1}, suggesting a v_S decrease in the uppermost inner core.

the outer liquid core is less dense than the pure molten iron at the same conditions of temperature and pressure, indicating the presence of light elements in the core, in an amount of about 10% by weight (Birch, 1964; Jephcoat and Olson, 1987; Poirier, 1994). Many candidates are possible. Sulfur has a great solubility inside liquid iron at core conditions; it is thus a possible candidate, but other elements such as O, N, Si, and K are likely to be present (Alfè et al., 2003; Andrault et al., 2009; Badro et al., 2007; Hirose et al., 2013; Poirier, 1994). The radioactive isotope ^{40}K, if present in the core, will be an additional source of energy to power the Earth dynamo. The presence of Ni (which has a higher density than Fe) in a proportion of about 4% is far from compensating the density decrease due to light elements (see **Chapters 2.06** and **8.02** for more details about the chemical state of the outer core).

The main questions relative to the fluid core concern its possible radial inhomogeneity, due in particular to the presence of these light elements. They are released at the ICB when the liquid iron alloy crystallizes, may migrate upward, and form a distinct alloy layer beneath the CMB. A stratification or a distinct layer at the top of the core is thus possible; it is predicted by thermodynamic models of core evolution (Buffett and Seagle, 2010; Lister and Buffett, 1998). It may influence the core–mantle coupling with consequences for Earth dynamics, nutations, and length of day and for the magnetic field (see **Chapter 3.10**). It may also give constraints on the nature of the light elements (Helffrich and Kaneshima, 2004). On the other hand, a dense layer at the base of the liquid core, due to heavy alloys, could bring information on the crystallization process of the inner core. A stratification may also result in variations of the thermal conductivity with depth. It is thus important to go in more details in the radial core structure. The periods of free oscillations indicate that the outer core is not strongly stratified (Masters, 1979). This is confirmed by the velocity profiles in global Earth models, which indicate radial homogeneity, except close to the core boundaries. If stratification is present, it will thus concern primarily the boundaries.

Lateral heterogeneities inside the liquid core are less probable, as an active convection is made possible by the low viscosity of the liquid alloy, comparable to that of water at the Earth surface ($\eta = 6 \times 10^{-3}$ Pa s, Poirier, 1988), or possibly slightly higher at the core boundary (Koot et al., 2010; Palmer and Smylie, 2005; Smylie, 1999; see also the review in Cormier et al., 2011). However, fluid motions in a rotating fluid sphere are organized in cylinders with axis parallel to the Earth's rotation axis (ERA) (Busse, 1975). The structures inside the cylinder tangent to the inner core are thus partly insulated from the fluid outside this tangent cylinder, being perhaps able to carry material with distinct properties. Sedimentation of a different material beneath the polar caps or the equatorial bulge may also be favored by the rotation.

The following sections present the seismological approach to these questions.

1.23.6.2 The Stratification at the Base of the Liquid Core

The propagation time of the PKP(BC) wave, which becomes diffracted along the ICB at large distance (giving the PKP(C_{diff}) wave), gives direct information on the structure of the lowermost 150 km of the liquid core. The velocities appear significantly lower than those of PREM, which roughly correspond to the adiabatic gradient (Souriau and Poupinet, 1991). This has been confirmed from waveform modeling of short-period records (Song and Helmberger, 1992, 1995a) and from other PKP(C_{diff}) observations (Zou et al., 2008). The data are well explained by a low velocity gradient in the lower 100–150 km at the base of the liquid core, where the velocity becomes nearly constant (**Figure 4(b)**). This low velocity gradient layer is sometimes improperly called the F-layer, in reference to a denomination of Bullen (1940). The anomalously low-amplitude decay of the diffracted waves PKP(C_{diff}) with distance (Song and Helmberger, 1995a; Souriau and Roudil, 1995) is another argument in favor of this low velocity gradient, which acts as a guide for the diffracted waves. However, the amplitude ratios of PKP(C_{diff})/PKP(DF) are close to PREM's predictions (Zou et al., 2008), an observation interpreted as due to either small-scale topography at the ICB or a thin sub-layer of relatively low-quality factor at the very base of the outer core.

A hemispherical pattern has been proposed for the low velocity layer (Yu et al., 2005), but the inner core structure could be responsible for this pattern as well (Cormier et al., 2011). Such a heterogeneity could not be sustained by the liquid unless its viscosity is very high (Cormier et al., 2011). This is not completely excluded: This layer could be a zone of small, nonzero rigidity ($v_S = 0.1$–0.5 km s^{-1}), as revealed by both normal modes (Mochizuki and Ohminato, 1989) and PKiKP waves reflected at the ICB (Cormier, 2009); thus, it could also be a zone of increased viscosity. The free inner core nutations suggest a viscosity of $\sim 10^5$ Pa s (Koot et al., 2010). The Slichter mode would be sensitive to such a layer (Smylie, 1999), but its identification on superconducting gravimeter records is highly controversial (Rosat et al., 2006).

Gubbins et al. (2008) have clearly shown that this low-velocity, high-density layer must be of compositional origin. In a slurry model, freezing and melting occur in this layer, and the P-velocity gradient is caused by a compositional gradient with heavy elements at the bottom. Melting appears necessary to generate this layer. Two mechanisms, which may coexist, have been invoked to produce melting: an inner core translation in the equatorial plane (Alboussière et al., 2010; Monnereau et al., 2010) and the thermal forcing by outer core convection (Gubbins et al., 2011). Alboussière et al. (2010) argue that melting on the inner core hemisphere exposed to pressure decrease during translation will produce a dense iron-rich liquid that spreads at the surface of the inner core. Gubbins et al. (2011) propose that melting occurs in response to heat transport by the outer core flow. This flow is driven by the large lateral variations of heat extraction at the CMB; it induces a large area of melting at the ICB under the Pacific and freezing mainly located under Indonesia.

1.23.6.3 The Stratification at the Top of the Liquid Core

The uppermost third of the core is mostly investigated with the S*m*KS wave, which becomes a whispering wave beneath the CMB for large *m* (*m* up to five has been observed as a distinct phase). Unfortunately, its travel time is strongly affected by the heterogeneities in the D″ layer, an effect that is only imperfectly corrected by the use of differential travel times between successive S*m*KS phases. Waveform modeling of S*m*KS may also be

used (Choy, 1977). Normal modes that sample the CMB region also provide useful information but, as previously said, they have poor depth resolution.

The different results do not lead to a consensus. Several studies implying different methods have proposed the presence of a thin (50–100 km thick) layer with slightly lower velocities at the top of the liquid core, which could correspond to an iron alloy enriched in light elements (Garnero et al., 1993; Helffrich and Kaneshima, 2010; Lay and Young, 1990; Tanaka, 2007). However, some studies fail to identify a distinct layer (Alexandrakis and Eaton, 2010; Helffrich and Kaneshima, 2004), while others detect a layer with increased velocity (Eaton and Kendall, 2006) or large-scale heterogeneities (Tanaka and Hamaguchi, 1993). The resolution of the different methods is, however generally not sufficient to discard the influence of lower mantle heterogeneities. It turns out that a thin uppermost distinct fluid layer is generally not required by the data (Garnero and Lay, 1998; Kohler, 1997).

Finally, the presence of a very thin, conductive, and slightly rigid layer of silicate deposits at the top of the core has been proposed to explain the amplitudes of the Earth nutations (Buffett et al., 2010). Even though normal modes may be compatible with a small amount of shear at the top of the liquid core (Romanowicz and Bréger, 2000), its seismological detection is still questionable (Rost and Revenaugh, 2001).

1.23.6.4 Search for a Three-Dimensional Structure Inside the Liquid Core

Gravitational forcing from the heterogeneities located inside the mantle and inner core (Piersanti et al., 2001; Wahr and de Vries, 1989) and steady-state dynamics must result in a 3D structure inside the fluid core. However, as shown by Stevenson (1987), the liquid core is not able to sustain relative density heterogeneities $\delta\rho/\rho$ larger than 10^{-4}. Assuming that velocity heterogeneities in liquid iron are proportional to density heterogeneities with a proportionality factor of -1 (Stevenson, 1987), the heterogeneities will be much below the level of detection by seismological methods. Despite this theoretical limit, several seismological results propose an outer core structure, that is, a departure from spherical symmetry (after ellipticity correction).

A large-scale aspheric structure in the liquid core is suggested by the splitting of some normal modes, which are difficult to explain by inner core and mantle structure alone (Ritzwoller et al., 1986; Widmer et al., 1992). Pushing to the extreme, it would be possible to explain the splitting of most of the core modes by outer core structure only (Romanowicz and Bréger, 2000), although the favored interpretation, which is more physically acceptable, is inner core anisotropy, as will be seen later.

A search for cylindrical structures related to the magnetohydrodynamic models of the core, such as embedded cylinders parallel to the ERA, has been performed using travel times of SKS and PKP(BC) and normal modes. No evidence of heterogeneity could be firmly established. PKP(BC) shows that P-velocities are identical inside and outside the tangent cylinder (Ohtaki et al., 2012; Souriau et al., 2003b; Yu et al., 2005), a result confirmed by normal mode analyses (Ishii and Dziewonski, 2005). It has also not been possible to detect P-wave anomalies beneath the polar caps nor beneath the equatorial bulge (Souriau et al., 2003b).

1.23.6.5 The Attenuation in the Liquid Core

Measurements of attenuation in the liquid core at high frequency (~1 Hz) are based on the amplitude of the phases P*n*KP reflected $(n-1)$ times under the CMB, with n up to 7 (**Figure 7**). The quality factor for P-waves, Q_α, is larger than 5000–10 000 (Cormier and Richards, 1976; Qamar and Eisenberg, 1974). Slightly lower values ($Q_\alpha = 1600$–7000, depending on frequency) are given by Tanaka and Hamaguchi (1996). Q_α may thus be considered as close to infinity. Such large values are not found elsewhere inside the Earth. Very large values are also obtained from normal mode analyses ($Q_\alpha = 12\,000$, Widmer et al., 1991), suggesting that Q is not strongly frequency-dependent inside the liquid core.

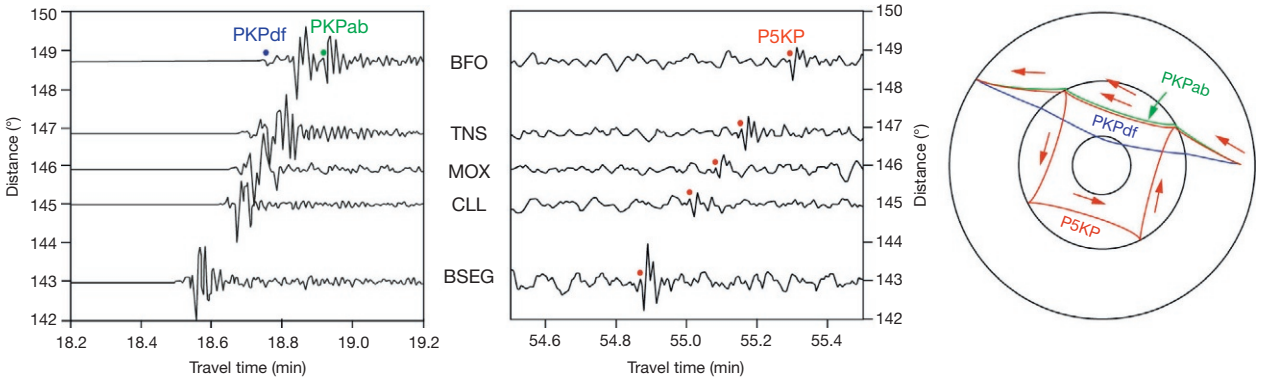

Figure 7 Right: Path of the P5KP wave inside the Earth (red), for a deep event of Fiji Island region (Dec. 18, 2000). The path of the PKP(AB) ray is superimposed (green); also shown is the PKP(DF) ray turning inside the inner core (blue). Left and middle: Waveforms of PKP and P5KP, respectively, recorded at different distances (station codes are between the two figures). The observation of P5KP on single records and its shape similarity with PKP(AB) are all together a proof of the lateral homogeneity of the liquid core, of its low attenuation, of the strong P-wave reflection coefficient underside the core–mantle boundary (which appears as a first-order discontinuity), and of the absence of significant topography at this boundary. Modified from Figure 11.71 of Bormann P, Klinge K, and Wendt S (2002) Chapter 11: Data analysis and seismogram interpretation. In: Bormann P (ed.) *IASPEI New Manual of Seismological Observatory Practice*, vol. 1, 102 pp. Potsdam: GeoForschungsZentrum; © IASPEI, with permission.

1.23.7 The Inner Core: Seismic Velocities

Seismic data have allowed us to establish the rigidity of the inner core, to specify its radial structure, and to detect long wavelength lateral variations. One of its most spectacular physical properties is its anisotropy, present in a large volume of the inner core: waves that propagate parallel to the ERA travel faster than those that propagate parallel to the equatorial plane. The anisotropy inside the inner core is however not uniform, with both radial and lateral variations. A hemispherical heterogeneity, which roughly distinguishes the Eastern and the western hemispheres defined with respect to the origin meridian, destroys the symmetry with respect to ERA. It is a very intriguing feature and a fundamental piece of information to understand how the inner core grows and how the anisotropy is generated.

1.23.7.1 S-Waves and the Rigidity of the Inner Core

Evidence of the rigidity of the inner core and v_S profiles inside the inner core have been mostly obtained by indirect observations. The observed periods of core-sensitive normal modes require rigidity (Dziewonski and Gilbert, 1971). They robustly constrain the mean value of the S-velocity to 3.5–3.6 km s^{-1} (Deuss, 2008; Dziewonski and Gilbert, 1971; Masters, 1979; Suda and Fukao, 1990), close to that of mean PREM. However, normal modes have no sensitivity at the Earth's center. The modeling of the PKP waveforms generally gives lower v_S values beneath the ICB, from nearly 0 (Choy and Cormier, 1983) to 2.5–4.0 km s^{-1} (Cummins and Johnson, 1988b; Häge, 1983; Müller, 1973). Amplitudes of the PKiKP reflected wave also favor a small v_S value at the ICB, of the order of 2–3 km s^{-1} (Cao and Romanowicz, 2004a; Koper and Dombrovskaya, 2005; Koper and Pyle, 2004; Shearer and Masters, 1990). Generally, these values are significantly lower than those given in global Earth models. Their compatibility with normal mode results implies the existence of a strong shear velocity gradient in the uppermost 200–300 km of the inner core (Cao and Romanowicz, 2004a; Choy and Cormier, 1983; Häge, 1983).

A direct evidence of the rigidity of the inner core relies on the detection of the phase PKJKP, which propagates as an S-wave inside the inner core and as a P-wave outside. Because of the very low amplitude of this phase, due to the strong shear-wave attenuation in the inner core, to the poor P- to S-wave conversion factor at the ICB, and to S-wave splitting due to anisotropy, there is no hope to observe PKJKP on single records. Stacking of several records is thus necessary to enhance the signal and even so is the success quite uncertain (Doornbos, 1974; Shearer et al., 2011). Optimal conditions are required for stacking, in particular, the appropriate phase velocity and distance and the appropriate frequency domain. This constitutes the major difficulty, because these conditions are poorly known. The distance at which PKJKP will have its maximum amplitude depends on the velocity and density contrasts at the ICB and on the S-velocity profile inside the inner core, which are not well known. In the worst case, if the S-velocity is close to zero at the top of the inner core (Choy and Cormier, 1983; Cormier et al., 2011), PKJKP will simply not exist. This may occur if a mushy zone is present at the top of the inner core. The frequency domain where PKJKP is observed is also unknown, although the strong attenuation inside the inner core suggests that it must be better detected on broadband records than on short-period records.

An identification of PKJKP on short-period records is proposed in three studies: Julian et al. (1972) proposed a very low S-velocity of 2.95 km s^{-1} in the inner core, whereas Okal and Cansi (1998) and Wookey and Helffrich (2008) found values close to those proposed in mean Earth models. Studies on broadband data have been conducted by Kawakatsu (1992), Deuss et al. (2000), Cao et al. (2005), and Shearer et al. (2011). Kawakatsu and Shearer et al. failed to observe PKJKP. Deuss et al. obtained a velocity of 3.6 km s^{-1} from the observation of a combination of two other parent phases (pPKJKP + SKJKP). Cao et al. obtained a clear phase arriving 9 s before PREM's predictions, implying that, if this phase is really PKJKP, v_S in the deep inner core must be about 1.5% larger than in PREM, where it is mostly constrained by normal modes sampling the outer part of the inner core. The two models may be reconciled if v_S increases with depth inside the inner core.

Most ab initio calculations on the elastic properties of iron crystals in the inner core display v_S values significantly higher than those inferred from seismology (Deuss, 2008; Vočadlo, 2007). This discrepancy has been used to support the presence of liquid in the inner core, resulting from dendritic solidification (Deguen et al., 2007; Singh et al., 2000; Vočadlo, 2007). Alternative explanations invoke the role of light elements and nickel, the presence of crystal defects that induces low rigidity (Belonoshko et al., 2007), or wave scattering by polycrystalline aggregates, in which wave velocity is decreased compared to that in single crystals (Calvet and Margerin, 2008).

1.23.7.2 The Anisotropy in P-Wave Velocity

The investigation of inner core anisotropy faces two major difficulties: (1) finding rays with various orientations turning in the same region at the same depth (from this point of view, the inner core sampling is very poor) and (2) getting rid of the perturbing contributions of the crust and mantle structures. Polar paths (i.e., paths parallel to ERA) are crucial, but they are rare, with an oversampling of the path from South Sandwich Island events to high-latitude stations, which often appear as anomalous (Tkalčić et al., 2002). In parallel, modeling relies on strong assumptions concerning the characteristics of anisotropy.

1.23.7.2.1 Evidence for anisotropy in P-wave velocity: early studies

The evidence of faster propagation along the polar axis than in the equatorial plane was first reported by Poupinet et al. (1983) from the analysis of the large amount of the PKP(DF) residuals collected by the ISC. This anomaly has been interpreted by Morelli et al. (1986) as due to inner core anisotropy. It is also well observed in the differential travel times of PKP(DF)–PKP(BC) and PKP(DF)–PKP(AB) (**Figure 8**). These observations confirm that the anomaly originates in the inner core, not in the liquid core or in the mantle (e.g., Creager, 1992; Shearer et al., 1988). On the other hand, the anomalous splitting of inner core-sensitive normal modes, which remains after correction for ellipticity and the Earth's rotation, is also well explained by anisotropy (Li et al., 1991; Tromp, 1993;

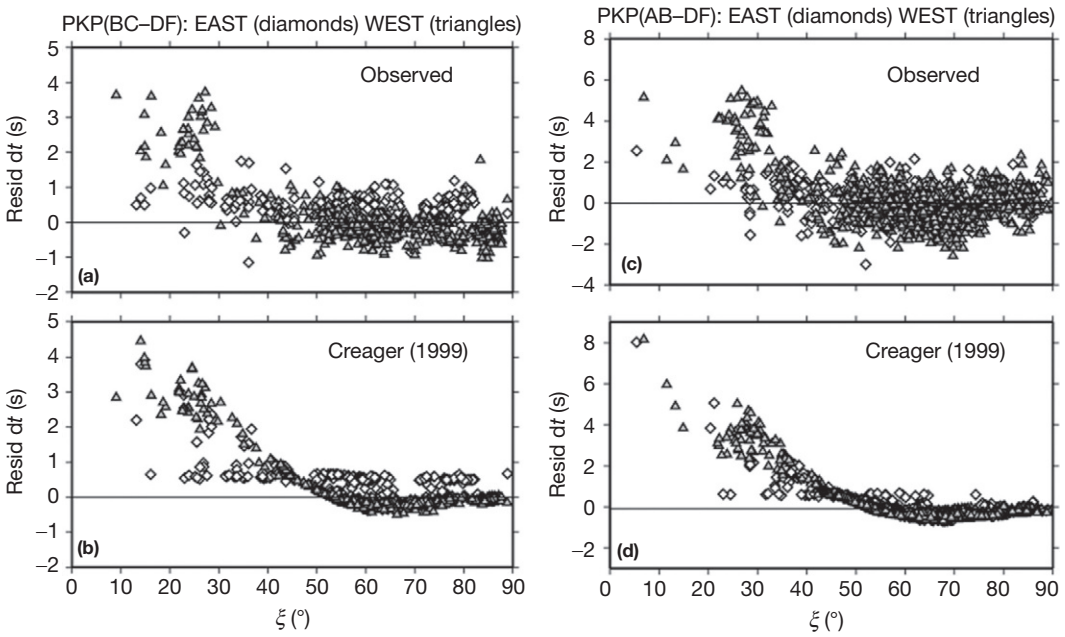

Figure 8 Evidence for anisotropy in the inner core. Differential travel time residuals for PKP(BC)–PKP(DF) (a) and for PKP(AB)–PKP(DF) (c) as a function of the angle ξ of the ray inside the inner core with respect to the Earth's rotation axis, distinguishing quasi-eastern (diamonds) and quasi-western (triangles) hemispheres (see **Section 1.23.7.2.2.2**). The high residuals at low ξ-values reveal that PKP(DF) polar paths are faster than equatorial paths. (b and d) Predictions of a cylindrical anisotropy model (transverse isotropy) by Creager (1999), with different coefficients for the two hemispheres. Reproduced from Romanowicz B, Tkalčić H, and Bréger L (2003) On the origin of complexity in PKP travel time data. In: Dehant V, et al. (eds.) *Core Dynamics*, *Structure and Rotation*. *Geophysical Monograph*, vol. 31, pp. 31–44. Washington, DC: American Geophysical Union.

Woodhouse et al., 1986). The travel time anomaly, after ellipticity correction, may reach up to 6 s for polar paths (Vinnik et al., 1994), compared to a total propagation time of about 1200 s through the Earth, of which about 220 s is through the inner core. Such a P-wave travel time anomaly is very large, compared to those observed for propagation through the mantle, which rarely exceed 2 s. A uniform cylindrical anisotropy (transverse isotropy), with a fast axis parallel to ERA and a level of anisotropy between 1.5% and 4%, explains the general features of the data (e.g., Creager, 1992; McSweeney et al., 1997; Morelli et al., 1986; Shearer, 1994; Song, 1996; Su and Dziewonski, 1995; Vinnik et al., 1994; see also a compilation of models in Ishii et al., 2002b). It is however insufficient to explain all the seismological observations, as a significant non-axisymmetric signal is also present (Su and Dziewonski, 1995) (see Tkalčić and Kennett, 2008, for a review of the first results).

One of the most commonly used expressions for representing inner core cylindrical anisotropy is (Su and Dziewonski, 1995)

$$\delta v_P/v_0 = a_0 + \varepsilon \cos^2\xi + \gamma \sin^2 2\xi \qquad [1]$$

where ξ is the angle between the ray inside the inner core and the symmetry axis. ε represents the P-wave anisotropy, that is, the difference between the P-velocity along the symmetry axis and the velocity perpendicular to it; γ is a mixed term that controls the P-wave propagation at intermediate angles; and a_0 represents a perturbation with respect to the P-velocity v_0 of the reference model. Many other equivalent expressions are also used in the literature (see equivalences in Calvet et al., 2006). The isotropic velocity is defined as the mean of the anisotropic velocity over the whole space (Creager, 1999), and its perturbation with respect to the reference model is given by

$$(\delta v_P/v_0)_{iso} = a_0 + \varepsilon/3 + (8/15)\gamma \qquad [2]$$

As will be seen hereafter, depth dependence and long wavelength variations are present in the anisotropy, thus, in the a_0, ε, γ parameters.

Some studies have proposed that the anisotropic symmetry axis could be slightly tilted with respect to ERA (Creager, 1992; Romanowicz et al., 1996; Su and Dziewonski, 1995). The data are well explained by such models, but the tilt is not required; it may result from the lack of data in some directions (Souriau et al., 1997). The question has also been raised whether the anisotropy could be an artifact due to mantle or liquid core heterogeneities that, because of their geographic distribution, may mimic a polar fast propagation (Bréger et al., 2000a,b; Ishii et al., 2002a; Romanowicz et al., 2003). Such a contribution is probable, but cannot fully explain the observations (Romanowicz and Bréger, 2000; Tkalčić et al., 2002). Anisotropy thus seems to provide the simplest explanation able to reconcile most of the seismological observations. We will specify hereafter its main characteristics.

1.23.7.2.2 Depth dependence of the anisotropy and hemispherical variations

The variation of anisotropy with depth is mostly deduced from the travel time anomalies of PKP(DF) as a function of epicentral distance for different ray orientations with respect to ERA. PKP(DF) is referred to the PKiKP reflected wave for sampling the uppermost 100 km, to PKP(BC) for the depth range 100–500 km, and to PKP(AB) at greater depths (**Figure 5(a)**).

1.23.7.2.2.1 The isotropic layer

There is a general agreement about a low level of P-wave anisotropy (<1%) in the uppermost 50–150 km of the inner core, with even perhaps no anisotropy at all (Creager, 1999, 2000; Garcia and Souriau, 2000b; McSweeney et al., 1997; Ouzounis and Creager, 2001; Shearer, 1994; Song and Helmberger, 1995b, 1998; Waszek and Deuss, 2011). Normal modes do not require this layer; they limit its mean thickness to 150–200 km (Durek and Romanowicz, 1999; Ishii et al., 2002a,b). Irving and Deuss (2011a) show that it is isotropic for both P- and S-waves. Some seismic observations favor a sharp discontinuity between the isotropic layer and the underlying anisotropic structure (Ouzounis and Creager, 2001; Song and Helmberger, 1998; Waszek and Deuss, 2011), but this is still controversial, as waves reflected at this discontinuity are not widely observed, and scattering from small-scale heterogeneities within the inner core may explain these observations as well (Leyton et al., 2005).

A hemispherical heterogeneity in this layer has been clearly identified by Niu and Wen (2001) from PKiKP and PKIKP records, the velocities in the quasi-eastern hemisphere (longitudes 40–180° E) being higher than in the Western one (**Figure 9**). This result reinforces previous sparse observations (Cormier and Choy, 1986; Kaneshima, 1996). It has been confirmed and refined by many other studies, which specify the level of heterogeneity in each hemisphere, the velocity gradient beneath the ICB, the depth to which the isotropic layer extends, and the longitudes of the transition between hemispheres (Cao and Romanowicz, 2004b; Garcia, 2002b; Waszek and Deuss, 2011; Wen and Niu, 2002; Yu and Wen, 2006a). For example, Yu and Wen (2006a) obtain a velocity gradient beneath the ICB that is larger in the quasi-western hemisphere than in the quasi-eastern hemisphere (5.0×10^{-4} and 0.4×10^{-4} (km s^{-1} km^{-1}, respectively), together with a smaller velocity jump at the ICB (0.65 and 0.75 km s^{-1}, respectively). There are significant variations among the different results: Irving and Deuss (2011b) give a difference in isotropic velocity of only 0.2% between the two hemispheres, Niu and Wen (2001) propose a value of 0.8%, Monnereau et al. (2010) obtain a value close to 0.5%, and Tanaka (2012) proposes 1.4% from equatorial paths. This hemispherical difference extends at least down 85 km beneath the ICB (Cao and Romanowicz, 2004b), possibly deeper (Tanaka, 2012; Yu and Wen, 2006a). The total thickness of the isotropic layer is also different for the two hemispheres, of the order of 100 km beneath the western hemisphere, extending deeper (400 km) beneath the Eastern one (Creager, 2000; Garcia and Souriau, 2000b). Monnereau et al. (2010) find a smooth transition between the two hemispheres, a result also supported by data sampling the high southern latitudes (Ohtaki et al., 2012). By contrast, Waszek and Deuss (2011) and Miller et al. (2013) propose sharp boundaries, but the same data may be as well explained by smooth variations in inner core texture from one hemisphere to the other (Geballe et al., 2013).

Heterogeneities in the isotropic layer are certainly present at other scale lengths. A broad, 3% low-velocity layer has been detected at the top 40 km of the inner core beneath equatorial Africa and the Indian Ocean (Stroujkova and Cormier, 2004). Local variations in the velocity at the ICB (Krasnoshchekov et al., 2005) or in the thickness of the isotropic layer (Yu and Wen, 2007) have also been proposed.

1.23.7.2.2.2 The anisotropy down to ~700 km depth

Beneath the isotropic layer, in the depth range 100–700 km for the quasi-western hemisphere and 400–700 km for the quasi-eastern one, anisotropy with fast axis parallel to ERA provides the simplest way to explain the dependence of P-wave velocity to ray angle ξ.

The difference between a strongly anisotropic quasi-western hemisphere and a weakly anisotropic quasi-eastern hemisphere is clearly pointed out by Tanaka and Hamaguchi (1997) from the differential travel times PKP(BC)–PKP(DF) (**Figure 10**). Creager (1999) found 2–4% anisotropy in the quasi-western hemisphere and only 0.5% in the quasi-eastern hemisphere. Other studies proposed an anisotropy level as high as 5% beneath the isotropic layer in the western hemisphere (Irving and Deuss, 2011b; Ouzounis and Creager, 2001). A mean value of 3% is generally accepted for the western hemisphere and 0.5–1% for the Eastern one.

The hemispherical pattern could partly be an artifact of the propagation through the lower mantle heterogeneities (Ishii et al., 2002a), but these heterogeneities fail to fully explain the observed pattern (Romanowicz et al., 2003). The South Sandwich Island events bias the polar path observations (Garcia et al., 2006; Tkalčić et al., 2002). Nevertheless, the hemispherical pattern in anisotropy seems to be a robust feature, and it is observed on both equatorial and polar data with opposite variations, as expected from relation [1] (Creager, 2000; Souriau et al., 2003a; Tanaka and Hamaguchi, 1997). In both hemispheres, the anisotropy is parallel to ERA. The isotropic velocity is nearly the same (Creager, 2000), which rules out an interpretation in terms of the difference in composition or fluid content. A variation in crystal alignment may explain the observations (Creager, 1999; Garcia, 2002b; Sun and Song, 2008). An alternative explanation invokes the difference in the thickness of the isotropic layer beneath the two hemispheres, which affects differently the PKP(DF) travel times so that it mimics variations in anisotropy (**Figure 10(c)**).

1.23.7.2.2.3 The innermost inner core

The presence of a different anisotropy in the central part of the core has been proposed to explain the travel time anomalies of PKP(DF) with nearly antipodal paths (Ishii and Dziewonski, 2002; Su and Dziewonski, 1995; **Figure 11**). A slow direction of propagation at about 45–55° from ERA is observed in the data sampling the innermost inner core (Calvet et al., 2006; Cao and Romanowicz, 2007; Ishii and Dziewonski, 2002, 2003; Niu and Chen, 2008; Sun and Song, 2008). Several studies have attempted to specify the anisotropy in this innermost inner core, with assumptions of transverse isotropy and symmetry axis parallel to ERA, but very different models have been obtained. Some models propose a fast axis parallel to ERA (Ishii and Dziewonski, 2003; Sun and Song, 2008) with a 3.5–3.7% anisotropy, higher than in the surrounding structures (**Figure 11(c)**, left). From a normal mode analysis, Beghein and Trampert (2003) propose a smooth model that favors a change in the sign of P-wave anisotropy in the central part of the inner core, thus an innermost inner core with a slow axis parallel to ERA (**Figure 11(c)**, right). An innermost inner core

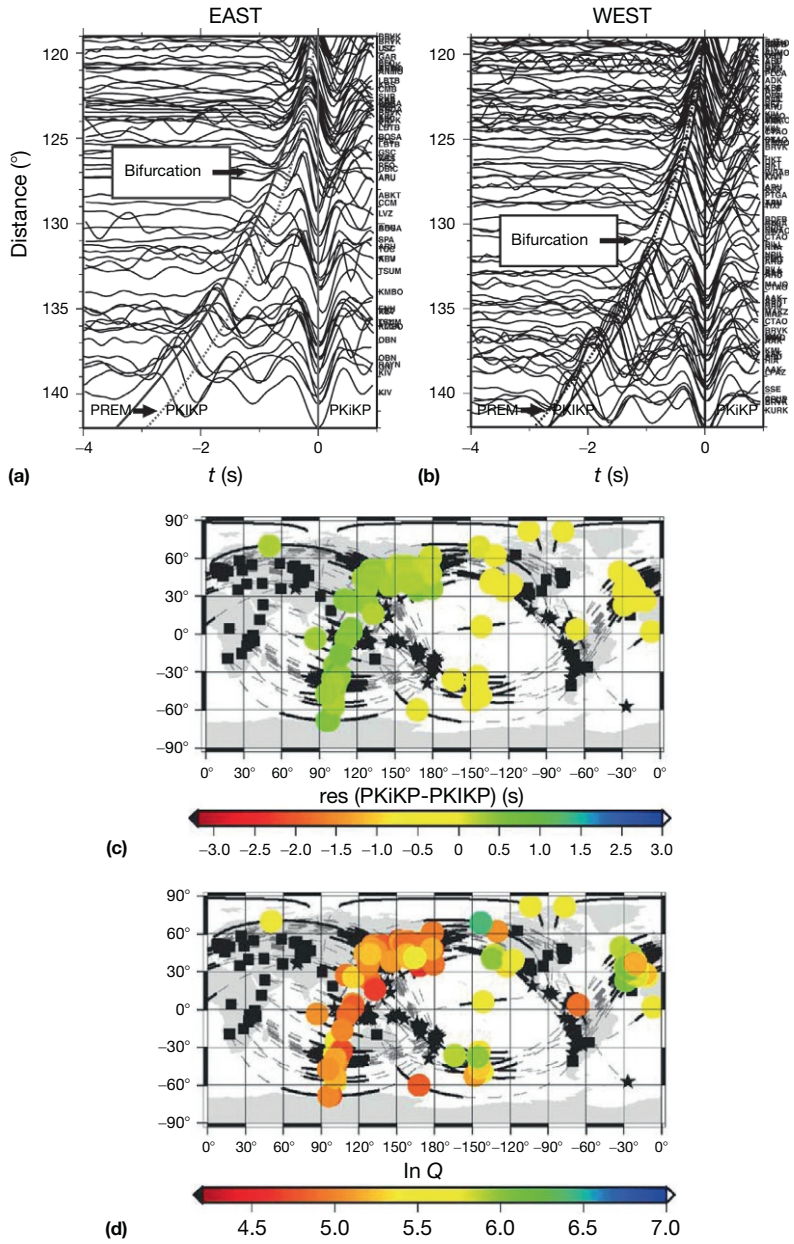

Figure 9 (a and b) Evidence for a hemispherical pattern in the uppermost inner core. Records of PKiKP and PKIKP phases sampling, respectively, the inner core boundary and the uppermost inner core beneath eastern and western hemispheres. The records are aligned on PKiKP, and the thick lines follow the phase maxima. Dashed line is the prediction for PREM. 'Bifurcation' corresponds to the separation of the two interfering phases. Note the difference between the two hemispheres for both differential travel times and PKIKP amplitudes, indicating a hemispherical heterogeneity in P-velocity and attenuation (reproduced from Wen L and Niu F (2002) Seismic velocity and attenuation structures in the top of the Earth's inner core. *Journal of Geophysical Research* 107 (B11): 2273). (c and d) Differential travel time residuals of PKiKP–PKIKP (in s) and quality factor (plotted in logarithmic scale) at the top of the inner core (depth 32–85 km below ICB, corresponding to distance 135–142°), showing that the eastern hemisphere is faster and more attenuating that the western hemisphere (reproduced from Cao A and Romanowicz B (2004) Hemispherical transition of seismic attenuation at the top of the earth's inner core. *Earth and Planetary Science Letters* 228: 243–253).

with P-wave anisotropy rate $\varepsilon = 0$ is obtained by Ishii et al. (2002a) (**Figure 11(c)**, middle). It turns out that, with the presently available data, the exact nature of the anisotropy in the innermost inner core is still hard to resolve and that the three families of models may be derived from the same PKP data, depending on data processing and assumptions used (Calvet et al., 2006). There is however some agreement about the mean radius of the innermost inner core, in the range 300–600 km for the most recent studies (Beghein and Trampert, 2003; Calvet et al., 2006; Cao and Romanowicz, 2007; Cormier and Li, 2002; Sun and Song, 2008). A sharp discontinuity at the top of the innermost inner core could not be detected (Cormier and Stroujkova, 2005; Garcia et al., 2006; Leyton et al., 2005; Niu and Chen, 2008). Cormier and

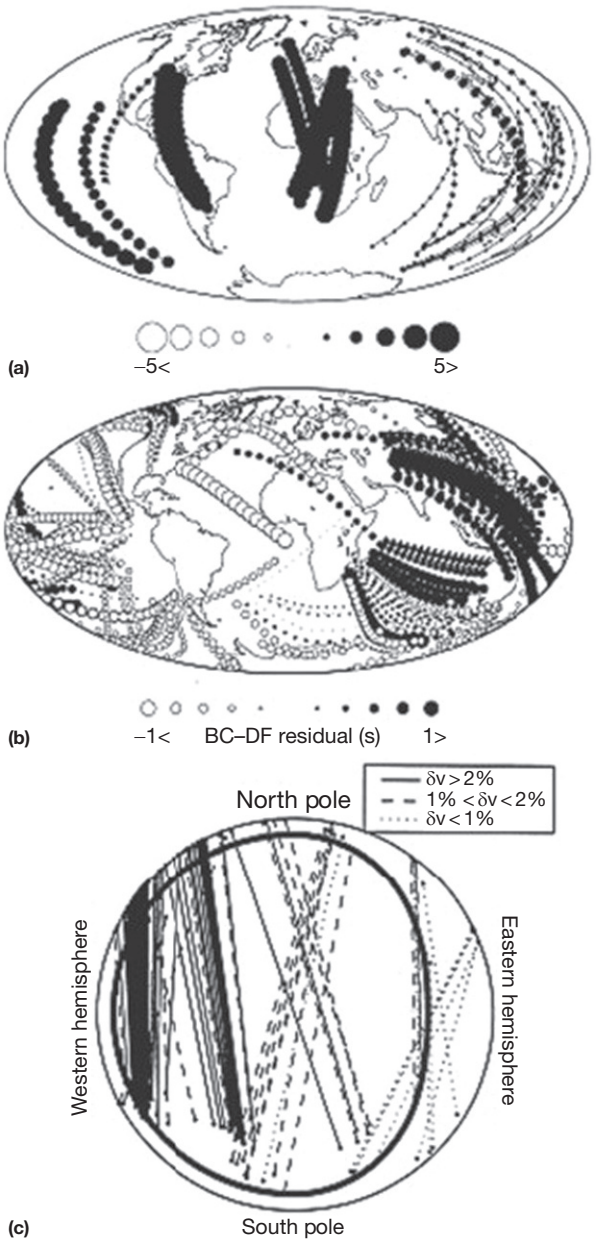

Figure 10 Evidence of a hemispherical pattern in the upper half of the inner core, as seen by PKP(BC)–PKP(DF) differential travel times. (a) Polar paths, the western hemisphere is faster than the eastern hemisphere; (b) the opposite is observed for East–West paths, but note the different scale (±5 s for (a), ±1 s for (b)) (reproduced from Tanaka S and Hamaguchi H (1997) Degree one heterogeneity and hemispherical variation of anisotropy in the inner core from PKP(BC)-PKP(DF) times. *Journal of Geophysical Research* 102: 2925–2938). (c) Interpretative cross section through the inner core looking from meridian 0°, showing the paths with their velocity anomalies, and a heavy line separating the isotropic asymmetric upper layer from the anisotropic structure (reproduced from Creager KC (2000) Inner core anisotropy and rotation. In: Dehant V, et al. (eds.) *Core Dynamics, Structure and Rotation*. *American Geodynamic Series*, vol. 31, pp. 89–114. Washington, DC: American Geophysical Union).

Stroujkova (2005) suggest the existence, between the two structures, of a broad, 50–100 km thick, transition zone at radius $r \sim 500$ km, which also coincides with a transition from low attenuation ($r < 500$ km) to high attenuation ($r > 500$ km) (Li and Cormier, 2002).

1.23.7.2.3 The origin of anisotropy

Seismic anisotropy in the inner core may be due to the preferred orientation of either anisotropic iron crystals, or elongated grains (each grain being an assemblage of crystals with similar orientations), or nonspherical fluid inclusions. In the first case, the seismic properties strongly depend on the elastic properties of the iron crystals and on their degree of alignment. In the second case, additional parameters are the orientation of crystals in each grain and the distribution of grain orientations in the medium. In the third case, the shape of inclusions and melt fraction are the key parameters.

The nature of iron or iron alloy at inner core conditions is a highly debated question. Details and references may be found in **Chapter 2.06**. The hexagonal closed-packed (hcp) structure of pure iron may be stable, but, because of the uncertainty on the temperature in the inner core, body-centered cubic (bcc), double hcp, and orthorhombic structures have also been proposed, on the basis of high-pressure experiments or theoretical computations. The presence of nickel or of light elements may stabilize the bcc or face-centered cubic phases. There is also no consensus on the elastic properties of the stable iron alloys and on the deformation slip system (Poirier and Price, 1999). Theoretical and experimental investigations on hcp iron have led to contradictory conclusions concerning the sign of P-wave anisotropy (fast or slow *c*-axis) depending on impurities and temperature, with even the possibility of a very low anisotropic rate. Iron in the bcc form, which is strongly anisotropic, provides an interesting alternative to hcp for explaining inner core anisotropy.

A degree of crystal alignment from 20% to 100% is necessary to explain the observed seismic anisotropy, depending on the elastic properties of the iron crystal. The distinct anisotropy in the innermost inner core suggests either the presence of a different iron phase (Kuwayama et al., 2008), or a different iron alloy, or some variation in the degree of crystal alignment. The reverse of the sign of the anisotropy at depth proposed by some seismic models may be explained by a variation with depth of the preferred orientation of a same form of iron.

A preferred orientation of ellipsoidal fluid inclusions is another possible mechanism to generate anisotropy (Singh et al., 2000). The presence of molten iron inclusions trapped in the iron lattice, at least in the upper half of the inner core, is proposed in support of the low S-velocity and high attenuation observed in that part of the inner core. The complex phase diagrams of iron alloys also favor a transition from solid to liquid with partial melting. A fluid volume fraction of 3–10%, present as oblate inclusions aligned in the equatorial plane, may explain the observed velocity anisotropy. However, as will be seen later, it fails to explain some characteristics of attenuation.

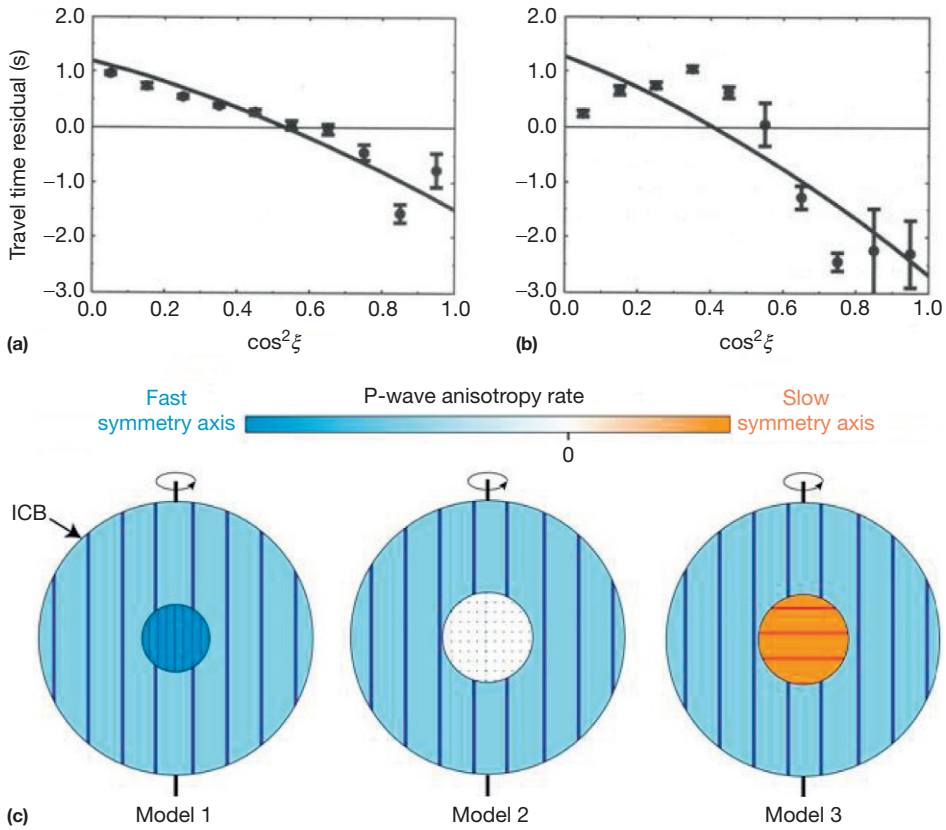

Figure 11 Evidence for a distinct anisotropy in the central part of the inner core. PKP(DF) residuals with respect to the reference model PREM, as a function of $\cos^2\xi$, where ξ is the ray angle with respect to the Earth's rotation axis inside the inner core (polar paths correspond to $\cos^2\xi = 1$). (a) Distance 153–155° (depth ~300 km beneath inner core boundary). (b) Distance 173–180° (turning point near the Earth's center). Black dots are the means of the observations with their error bars; thick lines are predictions for a uniform anisotropy model. Note on (b) the difference with the predictions for $\cos^2\xi \sim 0.35$ ($\xi \sim 55°$) ((a and b) reproduced from Ishii M and Dziewonski AM (2002) The innermost inner core of the Earth: Evidence for a change in anisotropic behaviour at the radius of about 300 km. *PNAS* 99: 14026–14030). (c) Cartoon showing the inner core with three possible innermost inner core structures that fit the data, with different P-wave anisotropy ((c) modified from Calvet M, Chevrot S, and Souriau A (2006) P-wave propagation in transversely isotropic media. II. Application to inner core anisotropy: Effects of data merging, parametrization and a priori information. *Physics of the Earth and Planetary Interiors* 156: 21–40).

The mechanism at the origin of a preferred alignment is also debated (see **Chapter 8.12** and Deguen, 2012, for reviews). The preferred orientation may be either acquired during the inner core growth (solidification texturing) or induced by deformation within the inner core. With solidification texturing, the internal structure is a record of inner core history since its formation, unless it has been erased by later processes. Solidification texturing may result from the growth of dendrites in the direction of heat extraction, thus in the radial direction with a cylindrical symmetry consistent with the convective pattern in the outer core (Bergman, 1997). Other texturing mechanisms able to generate anisotropy have been proposed, in particular alignment of iron crystal with the magnetic field (Karato, 1993) or compaction in the mushy zone at the ICB during inner core growth (Sumita et al., 1996).

Anisotropy may also result from inner core deformation. For example, it has been proposed that, because of the cylindrical pattern of the outer core flow that governs heat extraction, the inner core is expected to grow faster at the equator than near the poles. The adjustment of the inner core to its equilibrium figure is performed by a flow from the equator to poles (Yoshida et al., 1996), but the resulting deformation may be too weak to generate a substantial preferential orientation (Deguen, 2012). However, if the inner core has a compositional density stratification, the flow will be mostly concentrated in the upper layers, so that the central part of the core may keep the fossil texture of the primitive inner core (Deguen and Cardin, 2009).

Plastic deformation induced by convection inside the inner core may also produce anisotropy (Buffett, 2009; Cottaar and Buffett, 2012; Deguen and Cardin, 2011; Jeanloz and Wenk, 1988; Romanowicz et al., 1996; Weber and Machetel, 1992; Wenk et al., 2000). Convection may be driven by thermal or compositional instability in the inner core (Gubbins et al., 2013). The conditions required for triggering thermal convection are however not necessarily fulfilled, as they depend on debated parameters such as the thermal conductivity of iron, the amount of radioactive elements in the inner core, the conductivity profile of the outer core, and the heat flux at CMB (Buffett,

2000; Deguen, 2012; Hirose et al., 2013; Yukutake, 1998; see **Chapter 8.12**). Moreover, thermal convection hardly generates large-scale anisotropy, unless it is coupled with magnetic field (Buffett and Wenk, 2004; Karato, 1999).

1.23.7.3 Lateral Heterogeneities Inside the Inner Core and Scatterers

Lateral heterogeneities in the inner core may be due either to a change in isotropic velocity or to a change in anisotropy. In the first case (change in isotropic velocity), heterogeneities of thermal origin are ruled out, as the temperature is nearly uniform inside the inner core (Weber and Machetel, 1992). One may thus invoke either a chemical heterogeneity, a phase change, a change in the amount of partial melting, or a change in grain size of randomly oriented anisotropic grains. In the second case (change in anisotropy), the heterogeneity could be either an anisotropic domain with similar elastic properties but with different orientation or a domain with different anisotropic properties. Because of the poor geographic sampling, it is generally impossible to discriminate between bulk heterogeneities and anisotropy perturbations.

We have previously mentioned the existence of a hemispherical heterogeneity in isotropic velocity in the uppermost 85 km and a hemispherical variation in anisotropy in the depth range 100–700 km beneath ICB. We will later discuss the interpretation of this observation.

In the wavelength range 20–200 km, many studies have reported the possible existence of heterogeneities (Bréger et al., 1999; Collier and Helffrich, 2001; Creager, 1997; Kaneshima, 1996; Lindner et al., 2010; Song, 2000; Zhang et al., 2005). However, in none of these cases, it is possible to completely discard a mantle origin. A stochastic analysis of PKP(DF) at different distances shows that the heterogeneity in isotropic velocity does not exceed 0.3% for wavelengths 100–400 km (Garcia and Souriau, 2000b).

The existence of small-scale heterogeneities inside the uppermost inner core has been inferred from the observation of scattered energy in the coda of the PKiKP wave (Vidale and Earle, 2000). These scatterers raise great interest, because they may give information on the fine structure of the uppermost inner core, in particular on its possible dendritic growths and on the fate of grains and fluid inclusions with depth. They also contribute to the strong wave attenuation inside the inner core. The analysis of the PKiKP coda generally requires records from small aperture arrays (**Figure 12(a)**), in order to eliminate coda signal generated in the mantle or at the CMB. It is best observed in the frequency range 4–6 Hz (Koper et al., 2004; Poupinet and Kennett, 2004).

Two types of coda have been observed. In the first case, the signal may arrive emergently (**Figure 12(b)** and **12(c)**) with a spindle-shaped envelope lasting about 200 s after the theoretical arrival time of PKiKP, even if this phase is not observed (this is the case at distance ~70° because the reflection coefficient at the ICB is close to 0). This signal requires heterogeneities located in the uppermost 350 km of the inner core, with a size of the order of 1–10 km, and velocity contrast of 1–10%, or possibly more (Leyton and Koper, 2007a; Peng et al., 2008; Vidale and Earle, 2000). In the second case, the coda maximum is immediately after the PKiKP onset, with a rapid amplitude drop in the first seconds or tens of seconds, followed by a constant coda level during about 100–200 s (**Figure 12(d)**; Koper et al., 2004; Leyton and Koper, 2007b; Peng et al., 2008; Poupinet and Kennett, 2004; Vidale and Earle, 2000). Codas with sharp onsets may be better explained by scatterers at the ICB rather than in the inner core volume (Poupinet and Kennett, 2004; see **Chapter 1.24**).

Although the Earth sampling remains poor due to the limited number of small aperture arrays, the scatterer distribution appears uneven. The regions generating clear PKiKP coda are mostly beneath northern Pacific and eastern Asia, and the absence of coda is preferably observed beneath the Atlantic Ocean (Leyton and Koper, 2007b). This distribution may be related to the hemispherical pattern observed in the isotropic layer, even though additional observations are still necessary.

1.23.8 The Inner Core: Seismic Attenuation

The attenuation of seismic waves may give information on the physical nature of the inner core and on its texturing. In particular, if partial melting is present, a strong anelastic attenuation correlated with low S-velocities and low viscosity is expected. Energy loss may also be due to scattering induced by texture (anisotropic crystals with various orientations or shapes), by the presence of fluid pockets, or less likely by compositional heterogeneities. These two mechanisms induce wave dispersion thus PKP(DF) pulse broadening, but this effect is much more important for viscoelastic attenuation with flat relaxation spectrum than for forward scattering. The attenuation is usually quantified through the quality factor Q (attenuation is proportional to Q^{-1}). The total attenuation is expressed as the sum of anelastic (or intrinsic) attenuation Q_i^{-1} and scattering attenuation Q_s^{-1}:

$$Q^{-1} = Q_i^{-1} + Q_s^{-1} \quad [3]$$

(Sato et al., 2012).

P-wave attenuation Q_α^{-1} at high frequency is constrained by body waves, mostly by the amplitude of PKP(DF). For its anelastic contribution, Q_α depends on both the attenuation in bulk (Q_κ^{-1}) and in shear (Q_μ^{-1}), such as

$$Q_\alpha^{-1} = kQ_\mu^{-1} + (1-k)Q_\kappa^{-1} \quad [4]$$

where $k = 4/3 \times (v_S/v_P)^2$, v_P and v_S being the P- and S-velocities (see **Chapter 1.25**). Attenuation is also constrained by the normal modes, whose damping gives attenuation in the low-frequency part of the spectrum. Modes are mostly sensitive to the attenuation in shear and are insensitive to scattering by small-scale heterogeneities (<100 km). As for elastic parameters, they have a poor sensitivity to the central part of the core. A first difficulty in the interpretation of Q will thus result from the difference in the parameters and frequency bands sampled by body waves and normal modes. Another difficulty is to decipher the relative contributions of viscoelasticity and scattering.

1.23.8.1 P-Wave Attenuation: Depth Dependence and Hemispherical Variations

A comparison of the amplitude of PKP(DF) with the one of a nearby reference phase is often used to estimate the attenuation along the ray, using geometries that minimize source and mantle path contributions and assuming that Q is infinite in the liquid core. In the same way as for velocity models, the reference phase

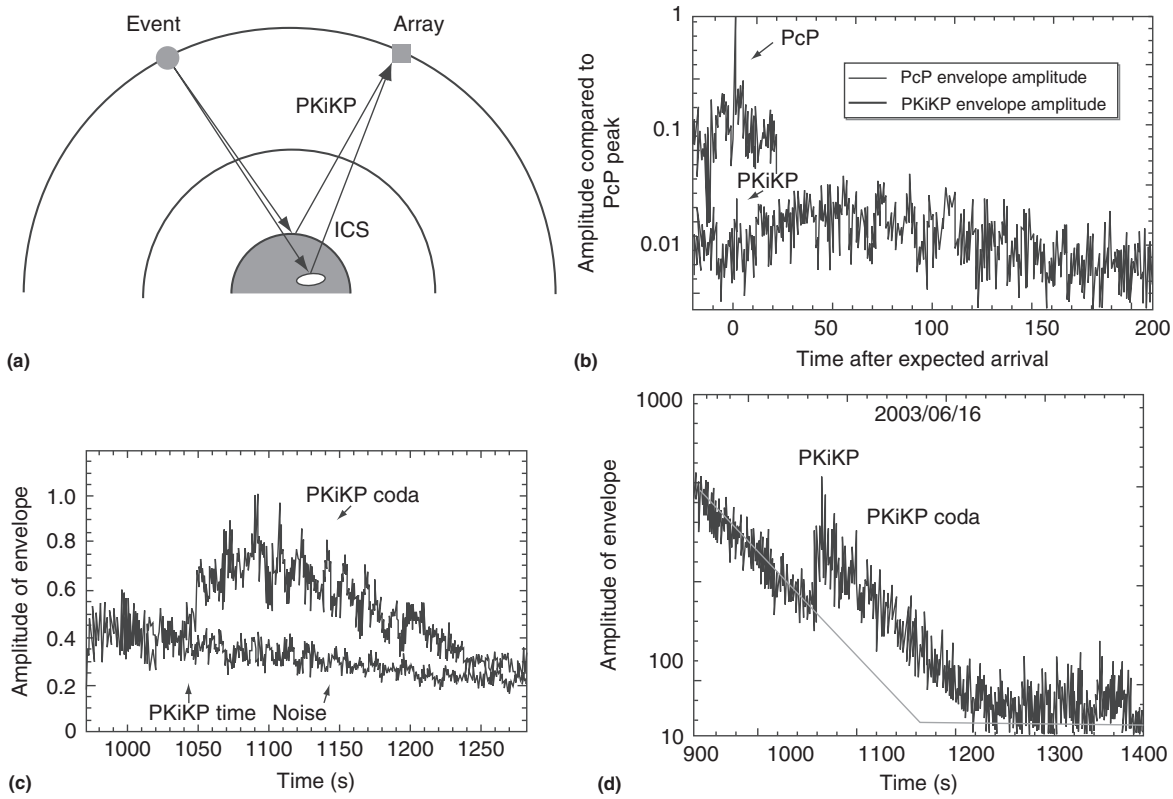

Figure 12 Detection of scatterers inside the inner core, from the coda of the PKiKP wave reflected at inner core boundary. (a) Principle of the method: energy arrival following PKiKP is detected at an array. (b) Comparison of the envelopes of the signal for the PcP wave reflected at core–mantle boundary and for the PKiKP wave, showing that the coda originates in the inner core, not in the mantle; the signals are stacks of two Novaya Zemlya nuclear tests. (c) Average of different PKiKP stacks for events at distances 60–70° from LASA in Montana, United States, compared to the noise ((a–c) reproduced from Vidale JE and Earle PS (2000) Fine-scale heterogeneity in the Earth's inner core. *Nature* 404: 273–275). (d) Same as (c) for an event at 74° from WRA array in Australia, showing a PKiKP coda with a different shape, an indication of variations in the scatterer properties inside the inner core ((d) reproduced from Poupinet G and Kennett BLN (2004) On the observation of high frequency PKiKP and its coda in Australia. *Physics of the Earth and Planetary Interiors* 146: 497–511).

is PKiKP in the uppermost 100 km and PKP(BC) for depths 100–300 km below the ICB with an extension down to 600 km using PKP(C_{diff}), but in this case, the amplitude of the reference phase becomes highly sensitive to the velocity gradient at the base of the liquid core. PKP(AB) is also sometimes used. The comparison of the two phases i and j is made either in the temporal domain, where the amplitude ratio A_i/A_j is measured on filtered traces, or in the spectral domain, taking advantage of the linearity of $\mathrm{Ln}(A_i/A_j)$ with frequency, if anelastic attenuation is dominant and not frequency-dependent. The intrinsic attenuation as a function of depth is then retrieved from the A_i/A_j ratio at different distances. A better approach uses waveform modeling, based on the comparison of the observed waveforms with the predictions of synthetic seismograms. It allows to sample any depth in the inner core, but it requires the knowledge of source and mantle structure (Li and Cormier, 2002; Tanaka, 2012).

The various studies come to a general agreement about a low Q_α in the uppermost inner core at frequency $f \sim 1$ Hz, with values ranging from 100 to 400 in the uppermost 200 km, increasing with depth up to 400–600 at 400 km beneath ICB (Bhattacharyya et al., 1993; Bolt, 1977; Cormier, 1981; Doornbos, 1974, 1983; Iritani et al., 2010; Ivan and Moloto-A-Kenguemba, 2007; Kazama et al., 2008; Niazi and Johnson, 1992; Ohtaki et al., 2012; Oreshin and Vinnik, 2004; Souriau and Roudil, 1995; Tanaka, 2012; Tseng et al., 2001; Yu and Wen, 2006a). These studies, which concern different regions, exhibit very different Q-profiles with depth. However, the error bars are large, and short wavelengths in mantle heterogeneities and CMB topography may strongly affect wave amplitudes (Bowers et al., 2000; Leyton and Koper, 2007a), which makes difficult the detection of regional variations, if any.

In the uppermost 50–100 km, a hemispherical pattern similar to the one observed for seismic velocities is clearly observed, the attenuation being stronger in the quasi-eastern hemisphere (40°–180° E) than in the quasi-western hemisphere (**Figure 9 (d)**). Q_α-values in the ranges 50–250 and 330–600 are reported for the eastern and western hemispheres, respectively (Cao and Romanowicz, 2004b; Garcia, 2002a; Monnereau et al., 2010; Tanaka, 2012; Wen and Niu, 2002; Yu and Wen, 2006a). Thus, high attenuation correlates with high velocity in the quasi-eastern hemisphere and low attenuation with low velocity in the quasi-western hemisphere. This correlation is opposite to that observed in the mantle, where it is ascribed to thermal effects. It is clearly detected down to 100 km but may be present deeper (Tanaka, 2012).

In the lowermost 500 km, waveform modeling of PKP at nearly antipodal distances reveals a Q-increase, together with a decrease in the scatter of the Q-values (Li and Cormier, 2002).

This central, high-Q zone approximately corresponds to the innermost inner core (**Figure 13**) and could correspond to a different fabric (Cormier and Stroujkova, 2005).

Studies based on spectral ratio analyses fail to detect a frequency dependence of Q_α in the narrow frequency range (0.2–2 Hz) sampled by body waves (e.g., Cormier, 1981; Souriau and Roudil, 1995), but waveform modeling, which takes into account the dispersive effect of viscoelasticity, suggests that such a frequency dependence is present (Cummins and Johnson, 1988b; Doornbos, 1983; Li and Cormier, 2002).

1.23.8.2 The Attenuation in Shear

The very strong attenuation in shear ($Q_\mu = 85$ in the PREM model) is mostly derived from the inversion of normal modes. Some specific studies of inner core-sensitive modes have proposed much larger Q-values, between 1500 and 4000 (Masters and Gilbert, 1981; Suda and Fukao, 1990), indicating that Q_μ must be high, about 3500. However, Widmer et al. (1991) have shown that these high Q_μ-values are possibly due to a misidentification of neighboring modes; they obtain $Q_\mu \sim 110$ for PKIKP-equivalent modes. On the other hand, Andrews et al. (2006) show that the Q-values may be affected by mode coupling and that Q_μ is low, so that the discrepancy between normal modes and body waves is small.

From waveform modeling of PKJKP, Cao and Romanowicz (2009) obtained a Q_μ-value of 315 ± 150. This is larger than the values given in PREM. As PKJKP better samples the Earth's center than modes, this discrepancy suggests that Q_μ increases with depth, as do Q_α and v_S.

The compatibility of modes and body waves has long been a subject of debate (see discussion in Romanowicz and Durek, 2000), because of the high Q_μ-values first proposed for inner core-sensitive modes. This seems no longer the case. However, the values of Q_α and Q_μ are not constrained well enough to infer the Q_κ value from relation [4], in particular to see if $Q_\kappa \gg Q_\mu$ as in the mantle. From the seismological results, it is also not possible to specify if several absorption bands are present in the inner core and what are the respective contributions of scattering and anelasticity.

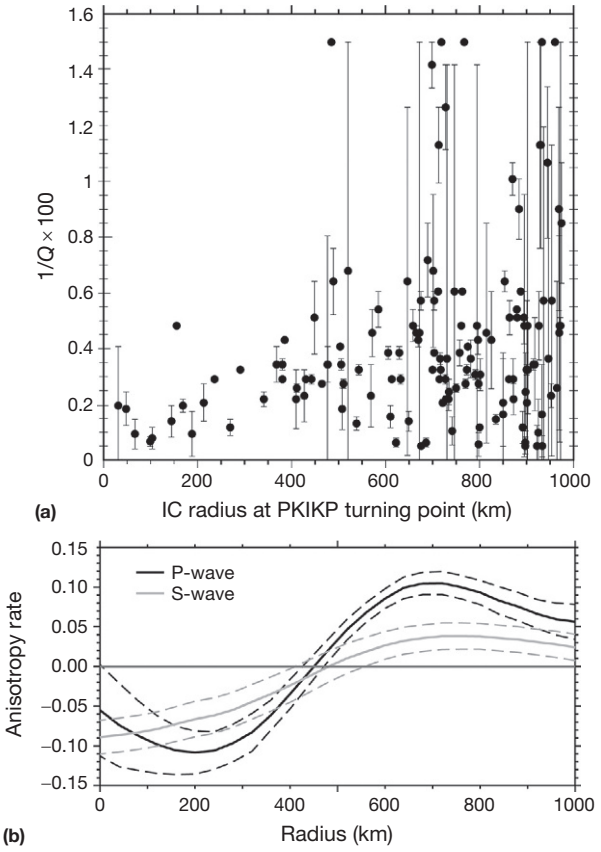

Figure 13 (a) Attenuation $1/Q_\alpha$ for PKP(DF) paths turning at different depths inside the inner core (Q_α is the P-wave quality factor) (reproduced from Cormier VF and Stroujkova A (2005) Waveform search for the innermost inner core. *Earth and Planetary Science Letters* 236: 96–105). (b) Two coefficients describing the anisotropy of P-wave velocity (black) and S-wave velocity (gray). Note the decrease of the attenuation and its smaller scatter inside the innermost inner core, where a different anisotropy is also observed (modified from Beghein C and Trampert J (2003) Robust normal mode constraints on inner core anisotropy from model space search. *Science* 299: 552–555).

1.23.8.3 The Anisotropy in Attenuation

A first direct evidence of anisotropy in P-wave attenuation is given by an analysis of PKP(DF) waves with turning points beneath the same region (Africa), but with various orientations with respect to ERA. Polar paths, which correspond to a faster propagation, also correspond to a stronger attenuation (Souriau and Romanowicz, 1996a; **Figure 14**). This result has been extended to the worldwide scale (Souriau and Romanowicz, 1996b) and to greater depth from waveform modeling of PKP at large distance (Cormier et al., 1998). Oreshin and Vinnik (2004) and Yu and Wen (2006b) confirm the dependence of attenuation with the ray angle with respect to ERA but show that it is observed in the western hemisphere only, where anisotropy in seismic velocity is the strongest one. Ray orientation also has an influence on the frequency dependence of attenuation and on dispersion (Souriau, 2009): For polar paths, the PKP(DF) wave is clearly dispersed and its amplitude decay is larger at high frequency than at low frequency, a frequency dependence that is not observed for equatorial paths.

From inner core-sensitive modes, Mäkinen and Deuss (2013) have identified a zonal pattern in anelasticity, suggesting that a cylindrical anisotropy in attenuation may also be present in shear, with again the high S-attenuation correlated to the high velocity.

1.23.8.4 Interpretation of Inner Core Attenuation

Two main mechanisms may contribute to attenuation: viscoelasticity (Cormier, 1981; Doornbos, 1974; Li and Cormier, 2002) and scattering (Calvet and Margerin, 2008; Cormier, 2007; Cormier and Li, 2002). They may be present simultaneously in the inner core.

A viscoelastic model with frequency-dependent attenuation is able to explain the main characteristics of attenuation in the body-wave domain (Li and Cormier, 2002), but the low dispersion of the data requires very particular conditions to be explained with this mechanism. Viscoelasticity could be

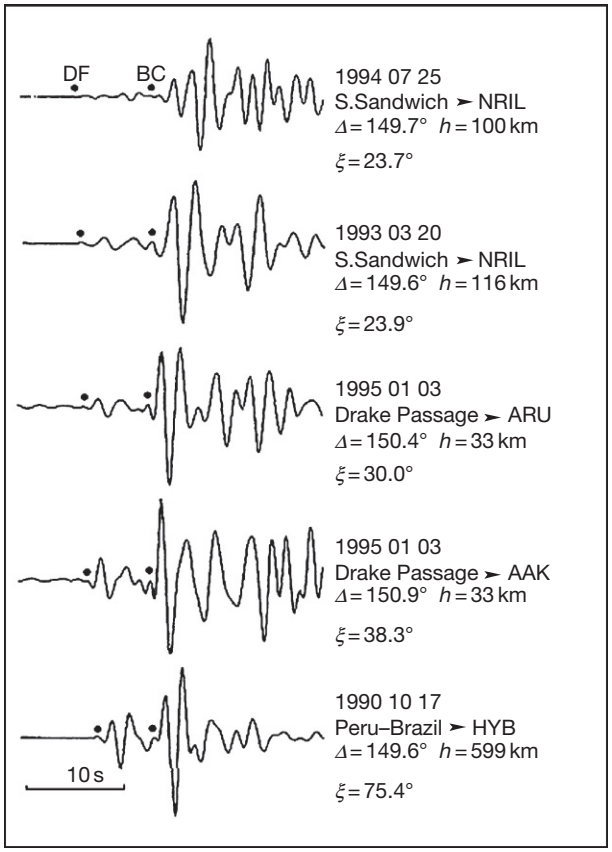

Figure 14 Evidence for anisotropy in attenuation correlated to the anisotropy in velocity, from records corresponding to paths turning in the inner core beneath Africa, with nearly the same distance Δ, but with different orientations ξ with respect to the Earth's rotation axis (h is the focal depth). PKP(BC) being the reference phase, note the fast propagation (large BC−DF time) and strong attenuation (small DF/BC amplitude) for nearly polar paths (small ξ). Data are band-pass filtered at 2 s. Reproduced from Souriau A and Romanowicz B (1996) Anisotropy in inner core attenuation: A new type of data to constrain the nature of the solid core. *Geophysical Research Letters* 23: 1–4.

present at the top of the inner core, because of a possible high proportion of fluid inclusions trapped in the iron lattice (Fearn et al., 1981; Loper and Roberts, 1981). However, the correlation of high (respectively low) attenuation with high (respectively low) velocity observed in the uppermost isotropic layer is opposite to model predictions (O'Connell and Budianski, 1977), which indicates that this mechanism is not predominant. From PKiKP coda analysis, Leyton and Koper (2007b) obtained a coda Q-value close to 500 and inferred that scattering attenuation must be at least comparable, or possibly larger, than anelastic attenuation in the uppermost inner core.

The difficulties met with the anelastic model are overcome with a scattering model Cormier (2002). The observation of PKiKP coda is a strong argument in favor of this mechanism. Scattering attenuation depends on the typical scale length of the heterogeneities and on the amplitude of velocity perturbations. The PKP(DF) attenuation may be explained by a heterogeneous random medium with P-wave velocity perturbations of ~8% and typical scale lengths 0.5–2 km (Cormier et al., 1998) or slightly larger, about 10 km (Cormier and Li, 2002). From the energy envelopes of PKiKP coda waves, Vidale and Earle (2000) found heterogeneities of about 2 km with velocity fluctuations of only 1.2% in the uppermost 300 km of the inner core. Cormier (2007) proposed that these coda waves are induced by reverberation on a platelike fabric developing at ICB under the shearing of the tangential outer core flow and obtained perturbations of 10%. Calvet and Margerin (2008) developed a scattering model in which the heterogeneities result from the random orientation of grains with similar anisotropy. They showed that iron grains of size ~400 m may easily explain Q_α-values in the range 300–600. The hemispherical variations may be due either to a variation of the preferred orientation in the texture (Cormier, 2007) or to a grain size difference between the two hemispheres (Monnereau et al., 2010). We will return to this point in the next section. On the other hand, from laboratory crystallization experiments and from geodynamic considerations, Bergman (1997, 1998) found a grain width around 200 m, which is in rather good agreement with seismological estimates.

The anisotropy in attenuation is too large to be explained by wave-front distortion due to velocity anisotropy. The correlation between anisotropy in velocity and anisotropy in attenuation, with the high attenuation axis corresponding to the fast axis parallel to ERA and low attenuation corresponding to slow propagation parallel to the equatorial plane, may give some indications about the mechanisms at the origin of anisotropy. If the velocity anisotropy were due to fluid inclusions, as proposed by Singh et al. (2000), the opposite correlation would be observed (Peacock and Hudson, 1990). The right correlation may be observed in anelastic anisotropic media characterized by complex stiffness tensor (Carcione and Cavallini, 1994). Again, scattering (by anisotropic crystals or elongated heterogeneities) appears to be the most plausible attenuation mechanism to explain the observed correlation for anisotropy. Following the dendritic model of Bergman (1997), Cormier (2007) proposed that radially oriented, elongated structures may explain both velocity and attenuation. The strong attenuation of paths parallel to ERA would be a consequence of the large number of grain boundaries crossed by the seismic rays.

Scattering is likely the predominant attenuation mechanism at high and intermediate frequencies (0.02–2 Hz) (Cormier and Li, 2002), but not in the normal mode frequency band (0.001–0.01 Hz) where viscoelasticity is favored. When scatterers cannot been directly detected from coda waves, deciphering the relative contributions of viscoelasticity and scattering relies on measurements of induced effects, such as pulse distortion or wave dispersion, which are difficult to observe (Cormier and Li, 2002; Li and Cormier, 2002).

1.23.8.5 Origin of the Hemispherical Pattern in the Uppermost Inner Core

The hemispherical pattern is certainly the most intriguing feature of the inner core. It appears at two levels: (1) in the uppermost isotropic layer, where the quasi-eastern hemisphere has high velocity and high attenuation compared to the Western one, and (2) in the depth range 100–700 km below ICB, where the western hemisphere has strong anisotropy in both velocity and attenuation with the fast axis and high

attenuation axis parallel to ERA, compared to the eastern hemisphere where anisotropy is weak for both velocity and attenuation. There is to date no satisfying explanation of these different observations. Scattering related to the iron crystal structure and diffusion related to fluid inclusions have both been invoked to explain the uppermost inner core dichotomy. Also, several geodynamic models are possible; some of them invoke simultaneous freezing and melting at ICB.

Cao and Romanowicz (2004b) argue that hemispherical variations of heat flow near ICB may induce variations in the melt fraction content and/or connectivity of liquid inclusions in a mushy zone. The liquid inclusions may be well isolated in the eastern hemisphere, while they may remain partly connected in the western hemisphere that may be colder and freezing more rapidly (Cao and Romanowicz, 2004b). The effect of the connectivity of fluids on the seismic properties is however highly complex (O'Connell and Budianski, 1977).

From laboratory experiments, it is inferred that textures acquired by solidification at the ICB may be closely coupled to heat extraction by the fluid flow at the base of the outer core (Bergman et al., 2002). Cormier (2007) proposes that, in actively crystallizing regions associated to outer core upwellings, the fabric is characterized by dendrites elongated in the radial direction with hcp iron c-axis perpendicular to the dendrite elongation (Bergman et al., 2002). This texture results in high velocity, strong PKP(DF) attenuation, and weak PKiKP coda (**Figure 15(a)**) and may represent the eastern hemisphere structure. By contrast, when the outer core flow is tangent to ICB, the longer scale lengths of the texture tend to be parallel to ICB, and the PKIKP attenuation is less efficient. Such a texture may develop in the western hemisphere where anisotropy is also observed. Lateral variations from strong to weak velocity and attenuation and from weak to strongly backscattered PKiKP coda may thus be explained by a textural variation from vertical- to horizontal-oriented platelike structures (Cormier, 2007). However, Cormier et al. (2011) argue that the long PKiKP codas observed by Peng et al. (2008) in the western hemisphere are better explained with an isotropic distribution of scale lengths (**Figure 15(b)**), together with viscoelastic dissipation.

Thermal heterogeneities may drastically affect fluid flow in the outer core, which in turn induces textural heterogeneity in the inner core (Sumita and Olson, 1999). Following this idea, Aubert et al. (2008) developed a model of thermochemical convection in the outer core, in which long-term cyclonic circulation beneath Asia causes fast freezing in the eastern hemisphere and slow freezing in the Western one where well-textured crystals develop (**Figure 16(a)**). The hemispherical texture and thermal conditions are thus opposite to those of Cormier et al. (2011) and Cao and Romanowicz (2004b). On the other hand, from geodynamo simulations, Gubbins et al. (2011) propose that melting and freezing may occur simultaneously at different places at the ICB, a broad melting zone being related to an outer core upwelling beneath the Pacific in the western hemisphere.

Thermal convection inside the inner core has also been proposed to explain the East–West seismic dichotomy. Convection with open boundaries (thus the possibility of freezing or melting at ICB) may induce a solid translation of the inner core (Alboussière et al., 2010; Monnereau et al., 2010). For large viscosity, the main convective mode is a global translation of

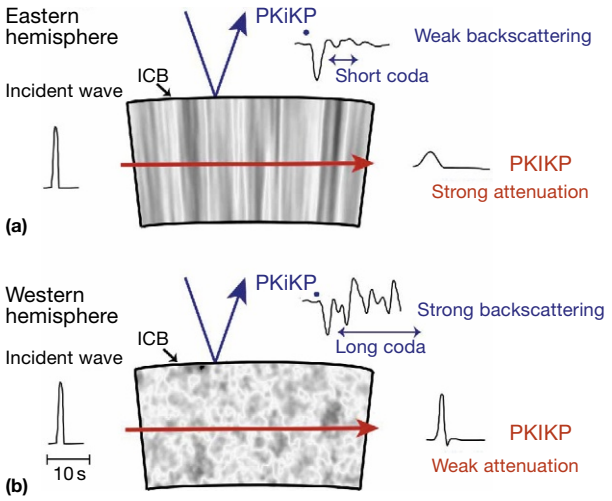

Figure 15 Possible textures explaining the hemispherical dichotomy in the uppermost inner core and their consequences for seismic waves. (a) Dendrites developing perpendicularly to inner core boundary (ICB), a possible model for the eastern hemisphere. The transmitted PKP(DF) wave (also noted PKIKP) is strongly dispersed and attenuated by the numerous boundaries encountered by the seismic ray (note the broadening of the signal), whereas the reflected PKiKP wave is almost undistorted. (b) Randomly distributed scatterers, a possible model for the western hemisphere. The strong backscattering is responsible for the long coda of transmitted waves. Modified from Cormier VF (2007) Texture of the uppermost inner core from forward- and backscattered seismic waves. *Earth and Planetary Science Letters* 258: 442–453.

the inner core with melting at the surface of one hemisphere and solidification at the other one (**Figure 16(b)**). Monnereau et al. (2010) suggest that grains grow during their transit from the crystallizing western hemisphere to the melting eastern hemisphere. Multiple scattering modeling of seismic waves in iron crystal aggregate explains the East–West dichotomy in both velocity and attenuation. The direction of translation and the resulting crystallizing hemisphere are however subjects of debate, as they depend on the forcing by thermal heterogeneities and on the liquid core flow; moreover, they may evolve with time (Aubert, 2013; Olson and Deguen, 2012).

The hemispherical pattern in anisotropy at depth is not fully explained by any models. For example, the translation mode does not produce any deformation. However, high-degree convective modes may develop for decreasing viscosity and induce texturing in the colder hemisphere (Mizzon and Monnereau, 2013). On the other hand, to explain the weak anisotropy in the eastern hemisphere, Bergman et al. (2010) suggest that the anisotropic solidification texture acquired in the western hemisphere is gradually lost during translation toward the melting side, as the result of thermal annealing.

1.23.9 Inner Core: Differential Rotation with Respect to the Mantle

A differential eastward rotation of the inner core with respect to the mantle (i.e., a faster rotation of the inner core) is predicted by some models of geodynamo (e.g., Aubert and Dumberry,

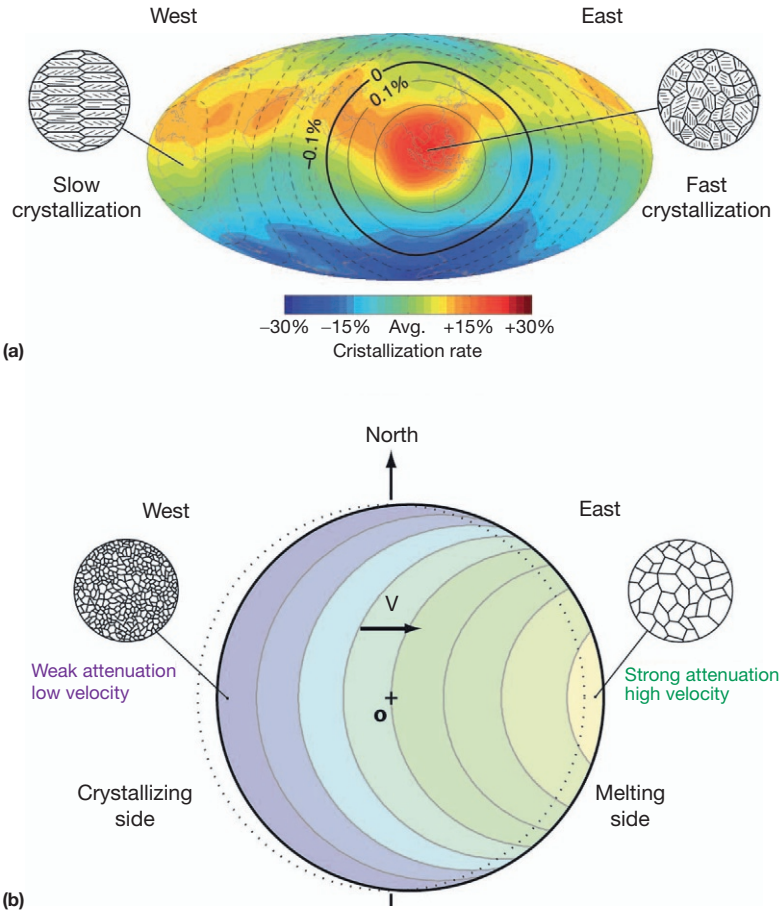

Figure 16 Cartoons illustrating two growth models at the origin of the seismic hemispherical pattern and possible resulting textures (grain size and orientation) in the uppermost inner core. (a) Relative crystallization rate (with respect to mean rate) at inner core surface resulting from heat extraction at ICB induced by the forcing of the thermal heterogeneities at CMB; superimposed is the seismic velocity degree one from Tanaka and Hamaguchi (1997) (modified from Aubert J, Amit H, Hulot G, and Olson P (2008) Thermochemical flows couple the Earth's inner core growth to mantle heterogeneity. *Nature* 454: 758–761). (b) Cross-section showing the age distribution in the inner core resulting from solid translation V (here from left to right, from dashed to plain positions). The age increases from the crystallizing side (blue) to the melting side (yellow) (reproduced from Monnereau M, Calvet M, Margerin L, and Souriau A (2010) Lopsided growth of Earth's inner core. *Science* 328: 1014–1017).

2011; Aurnou et al., 1996; Glatzmaier and Roberts, 1996; Gubbins, 1981; see Volume 8). The predicted rotation rate is as large as 2–3° year^{-1}; thus, time-dependent phenomenons induced by this rotation could possibly be detected by the propagation of seismic waves. At the same time, gravimetric coupling predicts that inner core heterogeneities and topography induced by mantle heterogeneities must be locked by the mantle gravity field, forcing the inner core to rotate at the same rate as the mantle (Buffett, 1997; see **Chapter 8.08**). Thus, the inner core rotation may give important constraints on the balance of these two antagonist effects and on their dynamic and structural consequences.

The basic idea for detecting inner core rotation is to track inner core heterogeneities during a long time, either along particular seismic paths that are unchanged during decades (**Figure 17(a)**) or at the worldwide scale. Seismological data are available since the 1950s, but high-quality digital data required for accurate analyses are available only since the 1980s. Before the 1970s, mechanical and optical limitations on recording systems made it hard to reach the accuracy level (< 0.1 s) required for such studies.

1.23.9.1 Tracking the Drift of a Heterogeneity Along a Stable Seismic Path

The heterogeneity could be either an identified small-scale heterogeneity inside the inner core (Creager, 1997; Lindner et al., 2010; Mäkinen and Deuss, 2011; Song, 2000), or the transition between the two inner core hemispheres (Souriau and Poupinet, 2003; Waszek et al., 2011), or scatterers (Vidale and Earle, 2005; Vidale et al., 2000), or the topography at ICB (Cao et al., 2007; Souriau, 1989; Wen, 2006).

Song and Richards (1996) proposed to use the apparent wobble of the tilted anisotropy symmetry axis, and, from the analysis of a 30-year data of South Sandwich Island events recorded at College Station (COL) in Alaska, they obtained a 1.1° year^{-1} eastward rotation rate. Soon after, another estimation at 3° year^{-1} was obtained from a worldwide analysis of

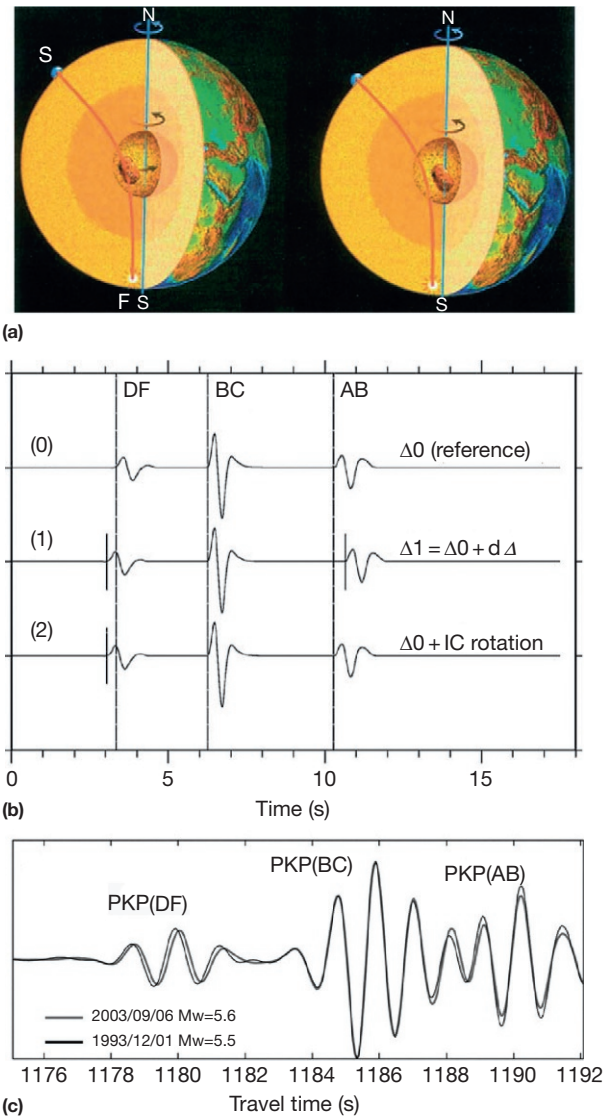

Figure 17 (a) Principle of the detection of an inner core differential rotation with respect to the mantle, from the drift of an inner core heterogeneity through a seismic ray. Figure on the right corresponds to a later stage than figure on the left, assuming an eastward (faster) rotation of the inner core. (b) Principle of doublets for discriminating between inner core rotation and earthquake mislocation, by the use of the three PKP phases (DF, BC, and AB). A small difference in location, giving a difference in epicentral distance $d\Delta$ with respect to the reference event at distance $\Delta 0$ (trace 0), results in a proportional variation of (BC−DF) and (AB−BC) (trace 1) compared to (0). Trace (2) corresponds to an event with same location as (0), but the DF time only is modified, due to the drift of an inner core heterogeneity along the DF ray ((b) reproduced from Souriau A, Garcia R, and Poupinet G (2003) The seismological picture of the inner core: Structure and rotation. *Compte-Rendus Geoscience* 335: 51–63). (c) Example of doublet of two South Sandwich Island events separated by 10 years (1993, 2003) recorded in Alaska. The DF time shift is interpreted as due to inner core rotation ((c) reproduced from Zhang J, Song X, Li Y, Richards PG, Sun X, and Waldhauser F (2005) Inner core differential motion confirmed by earthquake waveform doublets. *Science* 309: 1357–1360).

travel times (Su et al., 1996). These puzzling observations started an interesting debate that involved both observational and theoretical aspects, even though the interpretation in terms of tilt axis was criticized (Souriau et al., 1997). The data of South Sandwich Island events at COL were reinterpreted as due to the drift of a heterogeneity (Creager, 1997), leading to a rotation rate of 0–0.3° year^{-1}, depending on mantle heterogeneities. A difficulty arises from the perturbing signal of the subduction zones on both source and station sides. Paths that avoid subduction zones, for example, Novaya Zemlya nuclear tests recorded at Antarctic stations, led to time perturbations generally smaller than those observed for the path from South Sandwich Island to COL and sometimes of opposite sign (e.g., Isse and Nakanishi, 2002; Li and Richards, 2003b; Souriau, 1998). On the other hand, despite some attempts to retrieve simultaneously inner core structure and rotation, the existence of an inner core heterogeneity along the investigated path is generally difficult to assess (see Souriau and Poupinet, 2003; and Song, 2003, for reviews and discussions of the earlier results).

Another difficulty is to eliminate focal mislocations. Seismological networks have evolved with time, inducing systematic, time variable, location biases (Kennett and Engdahl, 1991) that could induce effects similar to those due to rotation. A way to circumvent this difficulty is to use doublets, that is, pairs of events with nearly the same focal location, recorded at the same station with similar waveforms (Poupinet et al., 1984). A difference in distance for the two events results in an apparent dilatation or contraction of one record with respect to the other (**Figure 17(b)**), whereas an inner core heterogeneity encountered along the path affects the PKP(DF) travel time only.

The doublet approach, first applied to the path from South Sandwich Island to COL (Poupinet et al., 2000), has been widely applied since. Despite the use of high-quality doublets, controversial results depending on the method refinement and on the paths considered have been obtained. In some cases, the same high-quality doublet (**Figure 17(c)**) recorded at different stations led to different interpretations involving either inner core rotation or variations in inner core radius (Cao et al., 2007; Wen, 2006; Zhang et al., 2005).

The results obtained along particular paths are globally inconsistent. Some of the paths give an eastward rotation, with rotation rates in the range 0.1–0.2° year^{-1} for most of them (Cao et al., 2007; Mäkinen and Deuss, 2011) and higher values (0.2 and 0.6° year^{-1}) for the paths from South Sandwich Island to Alaska (Lindner et al., 2010; Song, 2000; Tkalčić et al., 2013; Zhang et al., 2005). Some paths do not detect any variation (Collier and Helffrich, 2001; Isse and Nakanishi, 2002; Poupinet et al., 2000; Zhang et al., 2008) or a westward rotation (Mäkinen and Deuss, 2011). Nonmonotonic rotation (Lindner et al., 2010; Tkalčić et al., 2013) or inner core oscillations (Collier and Helffrich, 2001) have also been proposed. The incompatibility among the different paths led Mäkinen and Deuss (2011) to reject inner core rotation with rates exceeding 0.1° year^{-1}.

Scatterers inside the inner core may also be used. Their main advantage is the rapid modification of the diffraction

pattern when they move, thus the possibility to detect inner core rotation in a few years. Vidale et al. (2000) analyzed the scattered waves that follow PKiKP for two closely located Novaya Zemlya nuclear tests at 3-year interval and recorded at LASA (large aperture seismic array in Montana, United States). The change in the diffraction pattern may be explained by a $0.15^\circ\,\text{year}^{-1}$ faster rotation of the inner core. A similar analysis, carried out on seven Mururoa (Pacific Ocean) French nuclear tests recorded at NORSAR (Norway), gives a rotation rate of $0.05–0.10^\circ\,\text{year}^{-1}$ (Vidale and Earle, 2005). The location of the nuclear tests is however not known very accurately (within 5–10 km) so that systematic biases due to source location cannot be ruled out.

1.23.9.2 A Search for a Differential Rotation with a Worldwide Approach

Local or regional heterogeneities inside the inner core are difficult to identify; they may be hidden by mantle heterogeneities and are smeared by the PKP(DF) Fresnel zone. A way to avoid this problem is to solve inner core rotation at the worldwide scale.

Several studies are based on the data from the ISC catalog, using statistical approaches. The results are often poorly conclusive, either because of the uneven Earth sampling with time (Su et al., 1996) or because of the lack of resolution of the data (Souriau and Poupinet, 2003).

The most reliable results are obtained from the analysis of normal modes at two different epochs. They rely on the identification of long wavelength, even degree heterogeneities inside the inner core, after correction for mantle heterogeneities. Inner core heterogeneities are responsible for splitting of the resonance peaks, which are described by splitting functions whose time variations are analyzed. This method has the potential to estimate accurately the rotation rate, but a good Earth coverage and the use of a large number of modes are necessary. Sharrock and Woodhouse (1998) analyzed seven modes for the period 1977–96, and they obtained a westward rotation rate of $0.5–2.5^\circ\,\text{year}^{-1}$, depending on the mode considered. Laske and Masters (1999) analyzed a larger data set and found that the rotation rate is essentially zero over 20 years ($0 \pm 0.2^\circ\,\text{year}^{-1}$). A later study (Laske and Masters, 2003), with more modes and more events, shows that the results are consistent for different mantle corrections and again emphasizes the dependence of the result on the mode considered, with rotation rates either positive or negative (**Figure 18**). The mean eastward rotation rate is $0.13 \pm 0.11^\circ\,\text{year}^{-1}$, thus a rotation that is barely significant.

1.23.9.3 Rotation or No Rotation? Implications

After two decades of controversies, the absence of steady rotation now seems favored in the light of the most recent results, which show inconsistencies among the rotation rates obtained for different paths and for different normal modes. Note however that the resolution of the different methods hardly exceeds

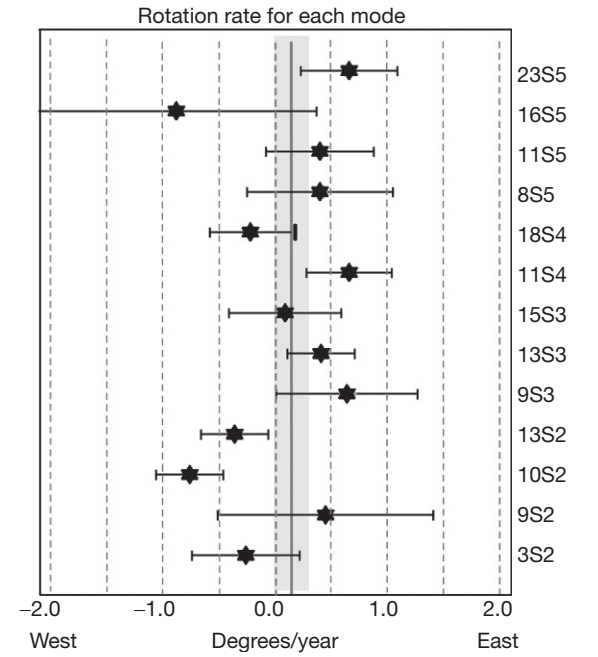

Figure 18 Inner core rotation rates obtained for various inner core-sensitive modes, after correction for mantle heterogeneities. The results vary with modes and are often compatible with a null rotation. Light gray area, least square fit of the rotation rate for all the modes. Modified from Laske G and Masters G (2003) The Earth's free oscillations and the differential rotation of the inner core. In: Dehant V, et al. (eds.) *Earth's Core, Dynamics, Structure, Rotation. Geodynamics Series*, vol. 31, pp. 5–22. Washington, DC: American Geophysical Union; Courtesy of G. Laske.

$0.05^\circ\,\text{year}^{-1}$, so that a rotation or oscillation rates lower than this value cannot be ruled out.

The largest rotation rates have been obtained for the paths from SSI to Alaska (time variations of $0.01\ \text{s year}^{-1}$ and rotation rates between 0.05 and $1.1^\circ\,\text{year}^{-1}$), which is the best sampled polar path. Unfortunately, it is also highly anomalous, as revealed by the large scatter of its PKP(DF) residuals (Bréger et al., 1999), and subject to criticism because of the difficulty to correct for mantle contributions and hypocentral mislocations. Moreover, PKP(DF) emerges barely from the noise, because of the strong attenuation in the polar direction (Li and Richards, 2003a). At the other end, the lower rotation rates are obtained from global studies, which are less dependent on the identification of a single heterogeneity. They are globally compatible with the absence of rotation. The analyses of reflected waves and scattered waves also lead to low rotation rates, $0.05–0.15^\circ\,\text{year}^{-1}$.

Whatever the path considered, and even for global Earth investigations, the main uncertainty concerns the heterogeneities that are used to quantify the differential rotation. The inner core sampling is generally too sparse to reliably map these heterogeneities. Only the quasi-hemispherical heterogeneity is robustly identified; temporal variations for this structure have been detected neither from body waves nor from normal modes (Souriau and Poupinet, 2003; Waszek et al., 2011).

The geodynamic consequences of an inner core rotation depend on the relative contributions of the gravitational, geomagnetic, and viscous couplings. These antagonistic effects may result in large ($\sim 0.1^\circ\,\text{year}^{-1}$) inner core oscillations with respect to the mantle about ERA, superimposed to a small steady rotation (Aubert and Dumberry, 2011; Buffett and Glatzmaier, 2000), but these results are strongly model-dependent. Some important parameters are the viscosity of the liquid core at the ICB and the viscosity of the inner core. The possible presence of a slurry layer above the ICB may contribute to increase the liquid core viscosity at the ICB. On the other hand, the inner core viscosity controls the ability of the inner core to deform in order to permanently adjust its shape to the mantle gravity field (Buffett, 1997).

If differential rotation is present, viscous deformation may concern the uppermost inner core only or the whole inner core, depending on the viscosity of the inner core. If the deformation is confined in an uppermost low viscosity layer, the strong shear induced by the viscous deformation would induce a preferred orientation of crystals or melt inclusions, in contradiction with the absence of anisotropy in the uppermost inner core. If the deformation involves the whole inner core, the inner core will be continuously mixed by the viscous flow, with relaxation times of the order of 3000 years. It will be hard in this context to maintain heterogeneities inside the inner core. Moreover, the readjustment flow will have a degree-two symmetry (Buffett, 1997); thus, it will induce a degree-four pattern in anisotropy, which is not observed. It is also difficult to reconcile a large rotation rate with the generation of a hemispherical pattern in the inner core, whose textural development requires a long-term coupling with the mantle, even though it is internally driven (see discussion in Deguen, 2012). A variation with depth of the hemispherical pattern, which could be a signature of the differential rotation during inner core growth (Waszek et al., 2011), may not easily be resolved with the seismological data because of the large Fresnel zone of the PKP waves. A large steady rotation thus seems unrealistic. This is consistent with dynamic models, which predict that the coupled effects of electromagnetic, viscous, and gravitational forces result in a mean rotation rate far below the detection threshold of seismological methods.

Inner core oscillations of the order of $0.1^\circ\,\text{year}^{-1}$ with typical period of 75 years are predicted from models taking into account the different torques acting on the inner core, although it must be noted that the fluctuations are far from being periodic (Aubert and Dumberry, 2011; Buffett and Glatzmaier, 2000). It has been suggested that the rotation observed in some studies could be part of an oscillation. This also seems unrealistic, because the different results relevant to a same time period do not give the same rotation rate (Mäkinen and Deuss, 2011).

The only way to reconcile the different observations is to imagine time-variable phenomena inside the inner core or at the ICB, which would have a local extension and which would be strong enough to give a seismological signature (Cao and Romanowicz, 2007; Mäkinen and Deuss, 2011; Sharrock and Woodhouse, 1998). It could be, for example, a modification in a slurry layer above ICB or in the mushy zone in the uppermost inner core. Alternatively, the source of variation could be outside the core. Finally, and more likely, the observations may still suffer from uncorrected mantle contributions and source location biases, even though doublet analyses remove most of them. In any case, more seismological and theoretical analyses are still necessary to make progress on this subject.

1.23.10 Conclusion

From the previous analyses, it may seem that the picture of the core is rather confused and that few characteristics meet a general agreement. This is true: the core is still a wide, almost virgin area of investigation compared to other structures in the Earth. Its deep location beneath heterogeneous layers (in particular D″ at the base of the mantle), together with the complexity of the physics of the core, let us anticipate that it will still long be a subject of controversy. At the same time, and for the same reasons, it is one of the most attractive objects for Earth scientists. We will attempt to summarize hereafter the seismological results that are considered as almost certain, those that are highly probable, and those that are still controversial or doubtful. We will then give some elements for future research.

1.23.10.1 Summary of the Results

The radii of the outer core and inner core are known with a good accuracy: 3480 ± 1 km for the CMB and 1215–1221 km for the ICB. These two boundaries are first-order discontinuities for the seismic waves (thickness < 2 km). The CMB has a small extra flattening (of < 500 m) with respect to its equilibrium figure and possibly a weak topography at different wavelengths, which may hardly exceed 4 km. The ICB has roughly the shape of its hydrostatic figure (thus is nearly spherical), with probably a long wavelength topography of no more than a few hundred meters, undetectable by seismology.

The liquid core is homogeneous from the seismological point of view, with neutral stratification except at the ICB, and perhaps at the CMB. Its density, well constrained by normal modes, shows a deficit with respect to molten iron that implies the presence of about 10% by weight of light elements. The base of the liquid core exhibits an ~ 150 km thick layer with low velocity gradient and increased density; it may correspond to an enrichment in iron. A repeated freezing and melting at the ICB is a possible mechanism to generate this layer. The liquid core has everywhere a nearly infinite quality factor. It is thus a transparent medium for seismic waves. It has a zero rigidity and a low viscosity; thus, it cannot sustain heterogeneities, except perhaps at the very base of the liquid core.

The ICB corresponds to an increase in P-velocity of about $0.7\ \text{m s}^{-1}$ and an increase in density of about $0.5–1.0 \times 10^3\ \text{kg m}^{-3}$, which indicate a strong depletion in light elements compared to the liquid core. The inner core is rigid, but the S-velocity profile inside the inner core is still poorly known. A lower shear velocity in the uppermost inner core suggests the presence of liquid inclusions. The P-wave quality factor Q_α is low (100–400) with scattered values in the uppermost 300 km. An increase of Q_α with depth is favored by most of the studies, and a rapid change in the characteristics of the attenuation seems to be present at radius ~ 500 km. The relative contributions of anelasticity and scattering in attenuation

are difficult to specify, and anelastic attenuation is probably present both in shear ($1/Q_\mu$) and in bulk ($1/Q_\kappa$).

The inner core is anisotropic in seismic velocities, with to the first approximation a cylindrical anisotropy (transverse isotropy) of 1–3% and a fast axis parallel to the ERA. The uppermost 100–150 km is almost isotropic. Anisotropy in attenuation is also present, with strong attenuation correlated with high velocities in the direction of the ERA. An innermost inner core with radius 300–600 km and an anisotropy different from that in the outer inner core have been detected, but the nature of the anisotropy inside this structure is still debated. It is also a zone of reduced attenuation.

A hemispherical pattern is present in the uppermost 600 km of the inner core, both for uppermost isotropic layer and for anisotropy. In the uppermost 80 km of the isotropic layer, the quasi-eastern hemisphere (40–180° E) has higher velocities and higher attenuation than the western hemisphere. In the depth range 100–600 km, the western hemisphere appears to be more anisotropic than the Eastern one for both P-velocity and attenuation. This dichotomy in anisotropy could be explained either by a variation in the degree of crystal alignment or by a difference in thickness of the isotropic layer, 400 km thick beneath the eastern hemisphere and only 100 km thick beneath the western hemisphere. The correlation between velocity and attenuation, opposite to that observed in the mantle, is best explained by scattering on iron anisotropic crystals or iron grains.

Small-scale lateral heterogeneities inside the inner core are hard to identify unambiguously. At very short wavelengths, scatterers of size 1–10 km have been identified inside the upper part of the inner core and at ICB from the coda of reflected waves. Their characteristics do not seem to be identical everywhere.

A search for a differential rotation of the inner core with respect to the mantle has led to very variable results, depending on the method and data used. Rotation rates from negative (westward rotation) up to more than $1^\circ\,\text{year}^{-1}$ (eastward rotation) have been obtained, large positive values being obtained along a few specific paths involving South Sandwich Island events and null rotation for worldwide analyses. Most of the recent results favor the absence of rotation or very small oscillations, in agreement with the predictions of geodynamic models.

Figure 19 summarizes the main results concerning the core.

1.23.10.2 Open Questions and Future Challenges

The distribution of inner core anisotropy with depth is an important issue. It could help specify the structure of iron in the inner core and how the anisotropy is generated. In parallel, the distribution of attenuation with depth and the S-velocity profile are important pieces of information to specify the texture and to detect partial melting.

The core boundaries are possible places of sedimentation, differentiation, and chemical exchanges that call for refined analyses. In particular, the ICB, which appears as a first-order discontinuity despite the possible presence of a mushy zone, remains to some extent enigmatic. An open question concerns the growing mechanism of the inner core, either from dendrites formed at the ICB or from a 'snow' of iron alloy formed in the lowermost liquid core. The relations between the uppermost inner core and the surrounding dense liquid layer have to be understood. Also, the possibility of liquid core layers with nonzero rigidity and increased viscosity at CMB and ICB deserve further exploration.

The East–West hemispherical pattern, which is a violation of the cylindrical symmetry imposed by the Earth's rotation, must be explained. Other degree-one structures exist in the Earth (e.g., the ocean–continent distribution). The existence of such a pattern in the uppermost inner core, without evidence of compositional heterogeneity, is a puzzling question. A model explaining simultaneously the hemispherical variations in the uppermost isotropic layer, those in anisotropy, and the presence of an innermost inner core has to be found, but a clear image of the inner core structure at depth is still missing.

The debate concerning inner core rotation with respect to the mantle is not completely closed. The origin of the highly varying rotation rates, depending on the method used and on the path considered, has to be understood. The numerous geodynamic problems related to a possible differential rotation or to inner core oscillations require that this question be definitively resolved.

Outside the field of seismology, many constraints are expected from the other domains of physics and chemistry. In particular, the improved performances of experimental and numerical simulations in high-pressure physics will hopefully give new constrains on the phase and texture present at the center of the Earth and on the light elements that could be incorporated in iron. Viscosity of the inner core is also an important parameter to specify, as it is related to thermal convection, deformation ability, and grain size, thus indirectly to anisotropy. On the other hand, geodynamo models including dynamic constraints will give new insights on inner core rotation or oscillations.

Through the different problems presented in this chapter, we have an appraisal of the numerous different fields of physics and chemistry involved in liquid core and inner core structure and dynamics. It seems now very important to favor strong interactions between the concerned scientific communities. This is particularly true for the modeling of the solid–fluid interactions and of the hemispherical pattern.

For seismology, improvements are expected in both observation and modeling. The numerical methods for computing synthetic seismograms in complex structures are important tools that could be more extensively used and that will still evolve. On the other hand, computation of scattered energy in complex media has still to be improved. From the experimental point of view, one of the most drastic problems remains the poor distribution of the data. This is particularly crucial for studying anisotropy, which requires a good sampling in all directions. The large unsampled provinces and the scarcity of polar paths illustrate the importance of maintaining observatories at high latitudes and of developing ocean-bottom observatories. A growing number of seismological studies process signals of very small amplitude, for which stacking is necessary. Permanent small aperture arrays, which are essential for such studies, are still missing at high southern latitudes. Finally, maintaining observatories for decades, despite the considerable effort it represents, is crucial to resolve inner core rotation and more generally to address time-dependent seismology.

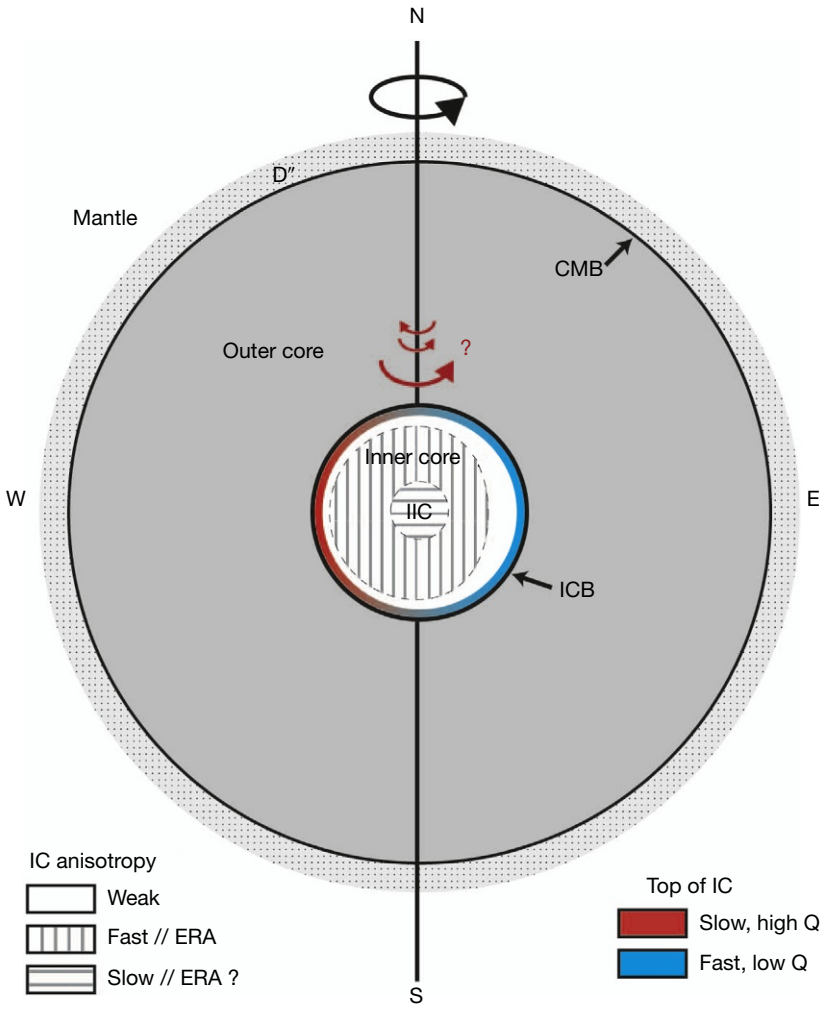

Figure 19 Cartoon of the structure of the core, summarizing the main seismological results: the absence of 3D structure in the liquid core, the existence of a nearly isotropic layer at the top of the inner core with a hemispherical pattern at the very top and a different thickness in each hemisphere, and anisotropy in the body of the inner core with fast axis parallel to the Earth's rotation axis. Still debated (or to specify) are the characteristics of the anisotropy in the innermost inner core and the differential rotation or oscillations of the inner core with respect to the mantle, although a null rotation rate seems now favored. IC, inner core; IIC, innermost inner core; ICB, inner core boundary; CMB, core–mantle boundary; ERA, Earth's rotation axis; Q, P-wave quality factor.

1.24.1 Introduction

Most seismic analyses of Earth structure rely on observations of the travel times and waveforms of direct seismic waves that travel along ray paths determined by Earth's large-scale velocity structure. These observations permit inversions for radially averaged P-wave and S-wave velocity profiles as well as three-dimensional (3D) perturbations. However, smaller-scale velocity or density perturbations cause some fraction of the seismic energy to be scattered in other directions, usually arriving following the main phase as incoherent energy over an extended time interval. This later-arriving wave train is termed the coda of the direct phase. Given the number of different scattering events and the complexity of the scattered wavefield, it is generally impossible to resolve individual scatterers. Instead, coda-wave observations are modeled using random media theories that predict the average energy in the scattered waves as a function of scattering angle, given the statistical properties of the velocity and density perturbations. In this way, it is possible to characterize Earth's heterogeneity at much smaller scales than can be imaged using tomography or other methods.

The fact that direct seismic waves can be observed in the Earth indicates that this scattering must be relatively weak so that a significant fraction of the seismic energy remains in the primary arrivals. In contrast, scattering on the Moon is proportionally much stronger than in the Earth, preventing the easy observation of direct P and S waves at global distances (at least at the recorded frequencies of the available data) and complicating inversions for lunar structure. In addition to facilitating observations of direct arrivals, weak (as opposed to strong) scattering also can simplify modeling by permitting use of single-scattering theory (i.e., the Born approximation). However, it is now clear that accurate modeling of scattering in the lithosphere, and possibly deeper in the mantle as well, requires calculations based on multiple-scattering theories. Fortunately, increased computer power makes these calculations computationally feasible.

Although both body waves and surface waves exhibit scattering, my emphasis in this chapter is on observations and modeling of deep-Earth scattering, for which body waves provide the primary constraints. In addition, I also will give more attention to the mantle and core than the lithosphere, which has been the focus of the majority of coda studies to date. Finally, I will only briefly summarize the different scattering theories. For more details on these topics, the reader should consult the book by Sato and Fehler (1998, 2012), which provides an extensive review of scattering theory and analysis methods, as well as a comprehensive summary of crustal and lithospheric studies.

1.24.2 Scattering Theory

Wave scattering from random heterogeneities is a common phenomenon in many fields of science, and theoretical modeling approaches have been extensively developed in physics, acoustics, and seismology. Solving this problem for the full elastic wave equation (i.e., for both P and S waves) in the presence of strong perturbations in the elastic tensor and density is quite difficult, so various simplifying approximations are often applied. These include assuming an isotropic elastic tensor, using first-order perturbation theory in the case of weak

 http://dx.doi.org/10.1016/B978-0-444-53802-4.00018-X

scattering, using the diffusion equation for very strong scattering, and assuming correlations among the velocity and density perturbations.

1.24.2.1 Single-Scattering Theory and Random Media

For sufficiently weak velocity and density perturbations, most scattered energy will have experienced only one scattering event and can be adequately modeled using single-scattering theory. The mathematics in this case is greatly simplified if we assume that the primary waves are unchanged by their passage through the scattering region (the Born approximation). The total energy in the seismic wavefield therefore increases by the amount contained in the scattered waves, and energy conservation is not obeyed. Thus, this approximation is only valid when the scattered waves are much weaker than the primary waves, which is the case in the Earth when the velocity and density perturbations are relatively small (quantifying exactly how small depends upon the frequency of the waves and the source–receiver distance). Single-scattering theory is sometimes called Chernov theory after Chernov (1960). Detailed descriptions of Born scattering theory for elastic waves are contained in Wu and Aki (1985a,b), Wu (1989), and Sato and Fehler (1998, 2012). A review of the properties (elasticity, conductivity, and permeability) and statistics of random heterogeneous materials is given in the text by Torquato (2002).

Single-scattering theory provides equations that give the average scattered power as a function of the incident and scattered wave types (i.e., P or S), the power of the incident wave, the local volume of the scattering region, the bulk and statistical properties of the random medium, the scattering angle (the angle between the incident wave and the scattered wave), and the seismic wave number ($k = 2n/A$, where A is the wavelength). A general random medium could have separate perturbations in P velocity, S velocity, and density, but in practice, a common simplification is to assume a linear scaling relationship among the perturbations (e.g., Sato, 1990) and/or to assume zero density perturbations. However, as pointed out by Hong et al. (2004), density variations can have an important influence on scattering properties. Performing the actual calculation for a specific source–receiver geometry involves integrating the contributions of small volume elements over the scattering region of interest. Each volume element will have a specific scattering angle and geometric spreading factors for the source–scatterer and scatterer–receiver ray paths.

The nature of the scattering strongly depends upon the relative length scales of the heterogeneity and the seismic waves. The scale of perturbations in a random medium can be characterized by the autocorrelation function (ACF), with the correlation distance, a, providing a rough measure of the average size of the 'blobs' in many commonly assumed forms for the ACF (e.g., Gaussian, exponential, and van Karman). Figure 1 shows examples of random realizations of the Gaussian and exponential ACF models. If the heterogeneity is large compared to the seismic wavelength ($a \gg \Lambda$, ka is large), then forward scattering predominates and becomes increasingly concentrated near the direction of the incident wave as ka increases. In the limit of large ka, the energy remains along the primary ray path and scattering effects do not need to be taken into account. Alternatively, if the blobs are small compared to the seismic wavelength ($a \ll \Lambda$, ka is small), then the scattering is often approximated as isotropic and the scattered power scales as k^4a^3. In the limit of small ka, the scattering strength goes to zero and the medium behaves like a homogeneous solid. As discussed by Aki and Richards (1980, pp. 749–750), scattering effects are strongest when a and A are of comparable size (i.e., when $ka \sim 2\pi$).

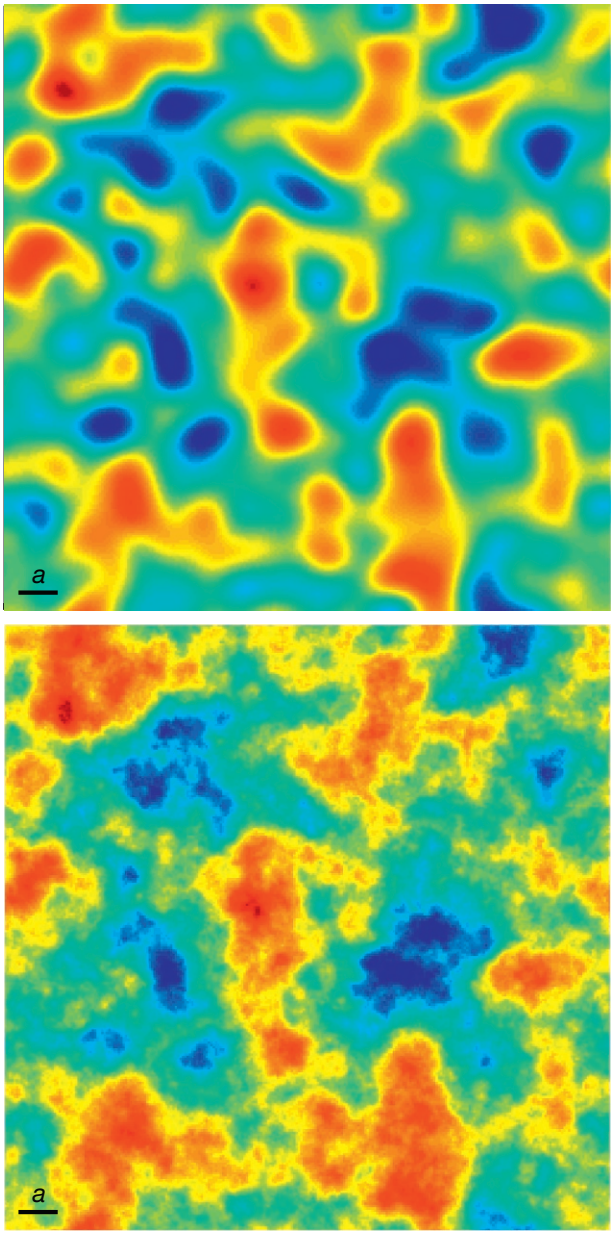

Figure 1 Examples of random media defined by a Gaussian autocorrelation function (top) and an exponential autocorrelation function (bottom). The correlation distance, a, is indicated in the lower left corner. The exponential medium has more structure at short wavelengths than the Gaussian medium.

Aki and Chouet (1975) presented an important application of single-scattering theory to predict coda decay rates for local earthquakes. For a colocated source and receiver and homogeneous body-wave scattering in 3D media, they obtained

$$A_C(t) \propto t^{-1} e^{-\omega t/2Q_C} \quad [1]$$

where A_C is the coda amplitude at time t (from the earthquake origin time) and angular frequency ω. Q_C is termed the coda Q, and there has been some uncertainty regarding its physical meaning, in particular whether it describes intrinsic attenuation, scattering attenuation, or some combination of both. I will discuss this more later in the context of more complete theories. Regardless of its interpretation, this formula has proven successful in fitting coda decay rates in a large number of studies.

Single-scattering theory has also been important for modeling deep-Earth scattering in terms of random heterogeneity models, including interpretation of PKP precursor observations (e.g., Doornbos, 1976; Haddon and Cleary, 1974), PP precursors (King et al., 1975), P′P′ precursors (Vinnik, 1981), P_{diff} coda (Earle and Shearer, 2001), and PKiKP coda (Vidale and Earle, 2000). Born theory has also been used to model expected travel-time variations in direct arrivals that travel through random velocity heterogeneity (e.g., Baig and Dahlen, 2004a,b; Baig et al., 2003; Spetzler and Snieder, 2001). Although my focus in this chapter is largely on incoherent scattering from random media, it should be noted that the Born approximation can also be used to model the effect of specific velocity structures, provided their perturbations are weak compared to the background velocity field. In this case, true synthetic seismograms can be computed, not just the envelope functions. For example, Dalkolmo and Friederich (2000) recently used this approach to model the effect of several different hypothesized velocity anomalies near the core–mantle boundary (CMB) on long-period P waves. In addition, Born theory forms the basis for computing sensitivity kernels in finite-frequency tomography methods (e.g., Dahlen et al., 2000; Nolet et al., 2005).

1.24.2.1.1 Q notation and definitions

Coda Q, intrinsic Q, and scattering Q will be termed Q_C, Q_I, and Q_{Sc}, respectively. P-wave and S-wave Q are termed ${}^{\alpha}Q$ and ${}^{\beta}Q$, respectively. These can be combined so that, for example, ${}^{\beta}Q_I$ is intrinsic S-wave Q. This convention eliminates any chance of confusing shear-wave Q and scattering Q (both have sometimes been termed Q_S). The transmission Q, Q_T, describes the total attenuation (both intrinsic and scattering) suffered by the direct wave

$$Q_T^{-1} = Q_I^{-1} + Q_{Sc}^{-1} \quad [2]$$

and the amplitude reduction of the transmitted pulse for a constant Q_T medium is

$$A(t) = A_0 e^{-\omega t/2Q_T} \quad [3]$$

where A_0 is the amplitude of the pulse at $t=0$ and we have ignored any geometric spreading.

The scattering coefficient, g, is defined as the scattering power per unit volume (e.g., Sato, 1977) and has units of reciprocal length. The total scattering coefficient, g_0, is defined as the average of g over all directions and can also be expressed as

$$g_0 = l^{-1} = Q_{Sc}^{-1} k \quad [4]$$

where l is the mean free path and k is the wave number. One common way to estimate g_0 for S waves has been to compare the energy in the S coda to the total radiated S energy. Finally, following Wu (1985), we define the seismic albedo as the ratio of scattering attenuation to total attenuation

$$B_0 = \frac{Q_{Sc}^{-1}}{Q_{Sc}^{-1} + Q_I^{-1}} = \frac{g_0}{g_0 + Q_I^{-1} k} \quad [5]$$

These definitions of Q, g_0, and B_0 are general and can be applied to the multiple-scattering theories discussed later in this chapter.

1.24.2.2 Finite-Difference Calculations and the Energy-Flux Model

Finite-difference methods provide a direct, albeit computationally intensive, solution to the seismic wave equation for media of arbitrary complexity, and they (together with the finite element method) have become one of the most widely used techniques in seismology. Their earliest applications to study scattering involved modeling surface-wave and body-to-surface-wave scattering from surface topography, sediment-filled basins, and other buried interfaces (e.g., Levander and Hill, 1985). Here, I will discuss only their use in modeling body-wave scattering in random media. Reviews of this topic are contained in Frankel (1990) and Sato and Fehler (1998, 2012).

As computing power has improved, finite-difference simulations have progressed from the 2D parabolic approximation, to 2D using the full wave equation, to full 3D synthetics. The parabolic approximation considers only forward scattering and is useful when the heterogeneity correlation length is large compared to the seismic wavelength. Complete finite-difference simulations in 2D random media have been performed by Frankel and Clayton (1984, 1986), McLaughlin et al. (1985), McLaughlin and Anderson (1987), Frankel and Wennerberg (1987), Gibson and Levander (1988), Roth and Korn (1993), and Saito et al. (2003). Frenje and Juhlin (2000) computed both 2D and 3D finite-difference simulations. Hong and Kennett (2003), Hong (2004), and Hong et al. (2005) used a wavelet-based numerical approach to compute 2D synthetics for random media and Hong and Wu (2005) computed 2D synthetics for anisotropic models.

The Frankel studies provided key results in formulating the influential energy-flux model (EFM) of seismic coda (Frankel and Wennerberg, 1987) so I will describe them in some detail. Frankel and Clayton (1986) modeled teleseismic P-wave travel-time variations with a ~1 Hz plane wavelet vertically incident on a layer 150 km wide by 55 km thick, with a finite-difference grid spacing of 500 m. They found that observed travel-time variations of about 0.2 s (RMS) among stations spaced 10–150 km apart could be explained with 5% RMS random P-velocity variations, provided the correlation length was 10 km or greater. Frankel and Clayton (1986) also modeled high-frequency coda from local earthquakes using a ~20 Hz explosive source at the bottom corner of a layer 8 km long by 2 km thick. They found that the amplitude of high-frequency coda depends strongly on the presence of high wave number velocity perturbations. Gaussian and exponential models with correlation lengths of 10 km or greater (required to fit observed teleseismic travel-time variations) do not have sufficient small-scale structure to produce observed levels of

high-frequency coda. In contrast, a self-similar random medium model with a correlation distance of at least 10 km and RMS velocity variations of 5% can account for both sets of observations.

By measuring peak amplitude versus distance in their synthetics, Frankel and Clayton (1986) estimated Q for their random medium. Because their finite-difference calculation did not contain any intrinsic attenuation, this represents a measure of scattering Q (Q_{Sc}). The predicted attenuation (Q^{-1}) peaks at ka values between 1 and 2 for Gaussian random media and between about 1 and 6 for exponential random media. This is consistent with the strongest scattering occurring when the seismic wavelength is comparable to the size of the scatterers. However, attenuation is constant with frequency for self-similar random media, as expected since the velocity fluctuations have equal amplitudes over a wide range of scales. Frankel and Clayton showed that these results were in rough agreement with those predicted by single-scattering theory in two dimensions (to match the geometry of the finite-difference simulations).

Frankel and Clayton (1986) also measured coda decay rates for finite-difference synthetics computed for sources within a 12 km by 12 km grid at 20 m spacing. They found that their observed coda decay rates were significantly less than those predicted by single-scattering theory in the case of moderate to large scattering attenuation ($Q_{Sc} \leq 200$), indicating that multiple scattering is contributing a substantial portion of the coda energy. This implies that in these cases, coda Q (Q_C) as determined from coda falloff and the single-scattering model of coda (e.g., Aki and Chouet, 1975) does not provide a reliable estimate of transmission Q.

Motivated by these finite-difference results and the limitations of the single-scattering model of coda generation, Frankel and Wennerberg (1987) introduced what they termed the EFM of coda. This phenomenological model is based on the idea that the coda energy behind the direct wave front can be approximated as homogeneous in space. This observation had previously been reported for microearthquake coda for lapse times more than twice the S-wave travel time (e.g., Aki, 1969; Rautian and Khalturin, 1978), and Frankel and Wennerberg (1987) showed that it also could be seen in finite-difference synthetics (see **Figure 2**). It implies that at sufficiently long times, the coda amplitude at all receivers is approximately the same (scaling only with the magnitude of the source), regardless of the source–receiver distance. The EFM permits the time decay of the coda amplitude to be modeled very simply and to separate the effects of scattering and intrinsic attenuation in the medium.

By considering the energy density of the coda uniformly distributed in an expanding volume behind the direct wave front, Frankel and Wennerberg derived an expression for the predicted time decay of the coda amplitude

$$A_C(t) \propto t^{-3/2} e^{-\omega t/2Q_I} \sqrt{1 - e^{-\omega t/Q_{Sc}}} \qquad [6]$$

where t is time, ω is angular frequency, Q_I^{-1} is intrinsic attenuation, and Q_{Sc}^{-1} is scattering attenuation. For short time and/or high Q_{Sc} (i.e., weak scattering, tQ_{Sc}^{-1} is very small), this equation reduces to

$$A_C(t) \propto t^{-1} e^{-\omega t/2Q_I} \qquad [7]$$

This is equivalent to the Aki and Chouet (1975) expression (eqn [1]) for the single-scattering model, assuming coda Q and intrinsic Q are equivalent ($Q_C = Q_I$). This agrees with the original interpretation of Q_C given by Aki and Chouet (1975) and contradicts the Aki (1980) statement that in the context of single-scattering theory, Q_C should be considered as an effective Q that includes both absorption and scattering effects. Frankel and Wennerberg (1987) showed that the EFM predicts the amplitude and coda decay observed in finite-difference synthetics for random media with a wide range of scattering Q and is more accurate than the single-scattering model for media with moderate to strong scattering attenuation ($Q_{Sc} \leq 150$). Finally, they used the EFM to estimate Q_{Sc} and Q_I from the coda of two $M \sim 3$ earthquakes near Anza, California.

There have been numerous other studies that have attempted to resolve Q_{Sc} and Q_I from local earthquake coda (e.g., Cirerone et al., 2011; Fehler et al., 1992; Jemberie and Nyblade, 2009; Mayeda et al., 1991; Padhy and Subhadra, 2010; Padhy et al., 2011; Toksöz et al., 1988; Wu and Aki, 1988). Notable are Mayeda et al. (1992), who analyzed S-wave coda from Hawaii, Long Valley, and central California. They found a complicated relationship between theoretical predictions and observed Q_C, Q_{Sc}, and Q_I and argued that models with depth-dependent scattering and intrinsic attenuation are necessary to explain their results.

The EFM was developed to explain local earthquake coda and finite-difference simulations of spherical wave fronts in media with uniform scattering. It is not directly applicable to modeling teleseismic coda because of the strong concentration of scattering in the crust and lithosphere compared to much weaker scattering deeper in the mantle. This has motivated the development of extended EFMs involving the response of one or more scattering layers to a wave incident from below (e.g., Korn, 1988, 1990, 1997; Langston, 1989).

The resulting formulas for the coda decay rate are more complicated than the simple EFM because they depend upon several additional parameters, including the travel time through the layer and the amount of leakage back into the half-space. Korn (1988) developed the theory for a spherical wave with a cone of energy incident upon a scattering zone

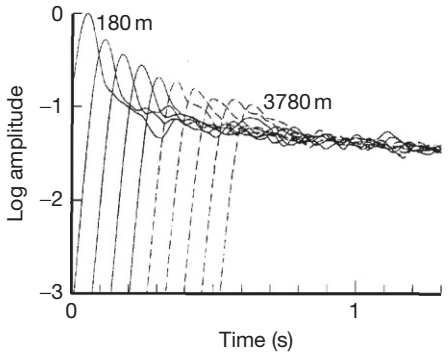

Figure 2 Envelopes of finite-difference synthetic seismograms for receivers at distances of 180–3780 m from the source as computed by Frankel and Wennerberg (1987) for a random medium with a correlation distance of 40 m. Note that the envelopes decay to a common level following the initial pulse, indicating spatial homogeneity of coda energy.

and used it to model regional earthquakes recorded by the Warramunga array in Australia. Langston (1989) developed a scattering layer-over-half-space model and showed that it was consistent with coda decay in teleseismic P waves recorded at two stations (named PAS and SCP) in the United States. Korn (1990) tested a scattering layer over homogenous half-space EFM using a 2D acoustic finite-difference code and found that it gave reliable results for both weak and strong scattering regimes. Korn (1997) further extended the EFM to explicitly include depth-dependent scattering and showed that it gave reliable results when compared to synthetics computed for a 2D elastic (P–SV) finite-difference code.

Wagner and Langston (1992a) computed 2D acoustic and elastic finite-difference synthetics for upcoming P waves incident on 150 different models of heterogeneous layers over a homogeneous half-space. These models varied in their layer thickness, random heterogeneity correlation length (different vertical and horizontal correlation lengths were allowed), and RMS velocity heterogeneity. They found that the scattering attenuation of the direct pulse depends upon ka and is strongest for spatially isotropic heterogeneity, in which case most of the coda energy was contained in low apparent velocity S waves and surface waves. In contrast, anisotropic models with horizontally elongated heterogeneities produce coda with mostly vertically propagating layer reverberations.

More recent finite-difference calculations for random media include the 2D whole-Earth pseudospectral calculations of Furumura et al. (1998) and Wang et al. (2001), Thomas et al. (2000) who computed 2D whole-Earth acoustic synthetics to model PKP precursors, Cormier (2000) who used a 2D elastic pseudospectral method to model the effects of D'' heterogeneity on the P and S wavefields, Korn and Sato (2005) who compared 2D finite-difference calculations with synthetics based on the Markov approximation, and Jahnke et al. (2008) who developed an axisymmetric finite-difference code suitable for parallel computers and showed how it can be used to model whole-mantle scattering at frequencies up to 0.4 Hz.

1.24.2.3 Multiple-Scattering Theories

If the energy in the scattered wavefield is a significant fraction of the energy in the direct wave, then the Born approximation is inaccurate and a higher-order theory should be used that takes into account the energy reduction in the primary wave and the fact that the scattered waves may experience more than one scattering event. These effects are all naturally accounted for using the finite-difference calculations discussed earlier, but these are computationally intensive and there is a need for faster approaches that also provide physical insight into the scattering process. In the case of very strong scattering, the diffusion equation can be applied by assuming a random walk process. Although this approach preserves energy, it violates causality by permitting some energy to arrive before the direct P wave. The first applications of the diffusion equation in seismology include the coda-wave analyses of Wesley (1965) and Aki and Chouet (1975) and the lunar seismogram studies of Nakamura (1977), Dainty and Toksöz (1977), and Dainty and Toksöz (1981).

At large times and small distances from the source, the diffusion equation predicts that the coda amplitude varies as

$$A(t) \propto t^{-3/4} e^{-\omega t/2Q_I} \quad [8]$$

where Q_I is the intrinsic attenuation. Notice that Q_{Sc} does not appear in this equation because the exact level of scattering is not important provided it is strong enough that the energy is obeying a random walk process. The diffusion equation can also be used to model the case of a strong scattering layer over a homogeneous half-space (e.g., Dainty et al., 1974; Margerin et al., 1998, 1999; Wegler, 2004), in which case an additional decay term exists to account for the energy leakage into the half-space.

Another approach to modeling multiple scattering is to sum higher-order scattered energy, and the predicted time dependence of scattered energy was obtained in this way for double-scattering (Kopnichev, 1977) and multiple scattering up to seventh order (Gao et al., 1983a,b). Hoshiba (1991) used a Monte Carlo approach (see the succeeding text) to correct and extend these results to tenth-order scattering. Richards and Menke (1983) performed numerical experiments on 1D structures with many fine layers to characterize the effects of scattering on the apparent attenuation of the transmitted pulse and the relative frequency content of the direct pulse and its coda.

Most current approaches to synthesizing multiple scattering use radiative transfer theory to model energy transport. Radiative transfer theory was first used in seismology by Wu (1985) and Wu and Aki (1988), and recent reviews of the theory are contained in Sato and Fehler (1998, 2012) and Margerin (2004). Other results are detailed in Shang and Gao (1988), Zeng et al. (1991), Sato (1993), and Sato et al. (1997). Sato and Nishino (2002) used radiative transfer theory to model multiple Rayleigh-wave scattering. Analytic solutions are possible for certain idealized cases (e.g., Sato, 1993; Wu, 1985; Zeng, 1991), but obtaining general results requires extensive computer calculations.

Two analytic results are of particular interest (and can be used as tests of numerical simulations). For the case of no intrinsic attenuation, Zeng (1991) showed the coda power converges to the diffusion solution at long lapse times

$$P_C(t) \propto t^{-3/2} \quad [9]$$

For elastic waves with no intrinsic attenuation, the equilibrium ratio of P and S energy density is given by (e.g., Papanicolaou et al., 1996; Ryzhik et al., 1996; Sato, 1994)

$$E_P/E_S = \frac{1}{2}(\beta/\alpha)^3 \quad [10]$$

Assuming a Poisson solid, this predicts about ten times more S energy than P energy at equilibrium, a result of the relatively low efficiency of S-to-P scattering compared to P-to-S scattering (e.g., Malin and Phinney, 1985; Zeng, 1993). For media with intrinsic attenuation, an equilibrium ratio also exists but will generally differ from the purely elastic case (Margerin et al., 2001a,b). Shapiro et al. (2000) showed that this ratio can be estimated from the divergence and curl of the displacement as measured with a small-aperture array and that its stability with time provides a test of whether the coda is in the diffusive regime.

Equation [10] is only valid for scattering within a uniform whole space and somewhat lower E_S/E_P ratios are expected at the surface of a uniform half-space. Margerin et al. (2009)

examined energy partitioning of seismic coda at Piñon Flat Observatory in California and obtained an average E_S/E_P ratio of about 2.8, over two times smaller than the expected value of 7.2 for equilibrium partitioning at the surface of a Poisson half-space. They explained their results by developing a theory of energy partitioning in a layered media and showed that E_S/E_P drops near the resonant frequency of a surface low-velocity layer. Thus, observations of equilibrium E_S/E_P ratios can provide information on local Earth structure. Margerin (2013) provided a theoretical treatment of multiple scattering and energy partitioning from randomly distributed point scatterers, which includes the effects of strong resonant scattering.

Wu (1985) used radiative transfer theory to address the problem of separating scattering from intrinsic attenuation. He showed that the coda energy density versus distance curves have different shapes depending upon the seismic albedo, B_0 (see eqn [5]), and thus, in principle, it is possible to separate scattering and intrinsic Q by measuring energy density distribution curves. Hoshiba (1991) pointed out that in practice, the use of finite window lengths for measuring coda will lead to underestimating the total energy (compared to the infinite lapse-time windows in Wu's theory), likely biasing the resulting estimates of seismic albedo. To deal with this problem, Fehler et al. (1992) introduced the multiple lapse-time window (MLTW) analysis, which measures the energy in consecutive time windows as a function of epicentral distance. The MLTW approach has been widely used in studies of S coda (see the succeeding text).

A powerful method for computing synthetic seismograms based on radiative transfer theory is to use a computer-based Monte Carlo approach to simulate the random walk of millions of seismic energy 'particles,' which are scattered with probabilities derived from random media theory. **Figure 3** illustrates a simple example of this method applied to 2D isotropic scattering. Variations on this basic technique are described by Gusev and Abubakirov (1987), Abubakirov and Gusev (1990), Hoshiba (1991, 1994, 1997), Margerin et al. (2000), Bal and Moscoso (2000), Yoshimoto (2000), Margerin and Nolet (2003a,b), and Shearer and Earle (2004). Because of the potential of the Monte Carlo method for modeling whole-Earth, high-frequency scattering, these results are now summarized in some detail.

Gusev and Abubakirov (1987) used the Monte Carlo method to model acoustic-wave scattering in a whole space and considered both isotropic scattering and forward scattering with a Gaussian angle distribution. They parameterized the scattering in terms of a uniform probability per unit volume, resulting in an exponential distribution of path lengths. Intrinsic attenuation was not included. They showed that their results agree with the diffusion model for large lapse times. Abubakirov and Gusev (1990) described in detail this method and its application to model S coda from Kamchatka earthquakes. They obtained an S-wave mean free path for the Kamchatka lithosphere of 110–150 km over a 1.5–6 Hz frequency range.

Hoshiba (1991) modeled the spherical radiation of S-wave energy in a constant velocity medium using a Monte Carlo simulation that included isotropic scattering with uniform probability. He showed that the results agreed with single-scattering theory for weak scattering (i.e., travel distances

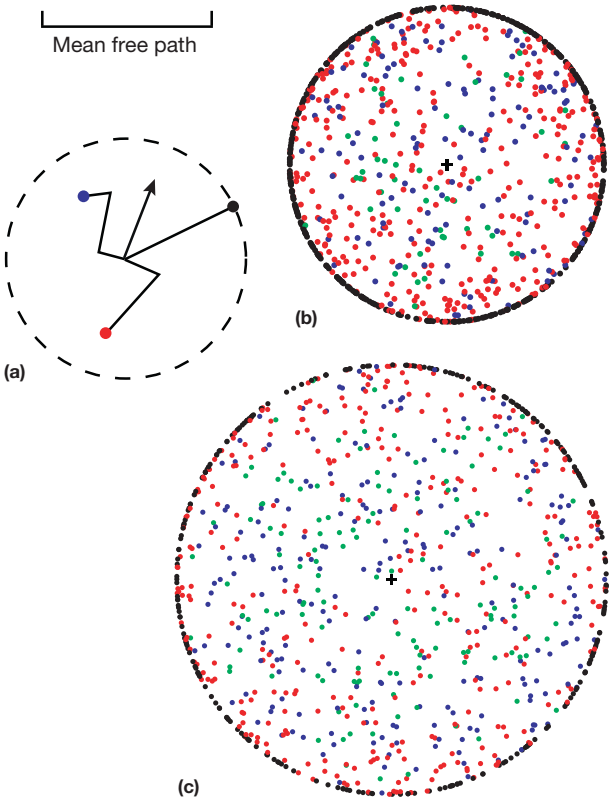

Figure 3 Example of a Monte Carlo computer simulation of random scattering of seismic energy particles, assuming 2D isotropic scattering in a uniform whole space. Particles are sprayed in all directions from the source with constant scattering probability defined by the indicated mean free path length, l. As indicated in (a), black dots show particles that have not been scattered, red dots show particles that have scattered once, blue dots show particles that have scattered twice, and green dots show particles scattered three or more times. (b) Results for 1000 particles after $t = 0.8/v$, where v is velocity. (c) Results for 1000 particles after $t = 1.25/v$. Note that the particle density is approximately constant for the scattered energy inside the circle defining the direct wave front, as predicted by the energy-flux model.

$<10\%$ of the mean free path) and agreed with the diffusion model for strong scattering (i.e., travel distances more than ten times longer than the mean free path). Hoshiba (1991) was able to use his Monte Carlo results to correct and extend the multiple-scattering terms of Gao et al. (1983a,b). He found that his simulations at long lapse times were consistent with the radiative transfer theory of Wu (1985) but that reliable estimates of seismic albedo are problematic from short time windows. Finally, Hoshiba (1991) showed that for multiple scattering, coda Q is much more sensitive to intrinsic Q than to scattering Q (as was argued by Frankel and Wennerberg, 1987, on the basis of the EFM).

Wennerberg (1993) considered the implications of lapse time-dependent observations of Q_C and methods for separating intrinsic and scattering attenuation with respect to the single-scattering model, Zeng's (1991) multiple-scattering model, Hoshiba's (1991) model, and Abubakirov and Gusev's (1990) results. Hoshiba (1994) extended his Monte Carlo method to consider depth-dependent scattering strength and intrinsic attenuation, and Hoshiba (1997) included the

effects of a layered velocity structure to model local earthquake coda at distances up to 50 km. Hoshiba simulated SH-wave reflection and transmission coefficients at layer interfaces as probabilities of reflection or transmission of particles in the Monte Carlo method but did not include P waves and the conversions between P and S waves. The results showed that coda amplitudes depend upon the source depth even late into the coda.

Margerin et al. (1998) applied the Monte Carlo approach to a layer over a half-space model, representing the crust and upper mantle, and included both surface- and Moho-reflected and transmitted phases. As in Hoshiba (1997), reflection and transmission coefficients are converted to probabilities for the individual particles. S waves only are modeled (using the scalar-wave approximation, i.e., no P-to-S conversions) and no intrinsic attenuation is included. Margerin et al. (1998) compared their numerical results in detail with solutions based on the diffusion equation and found good agreement for suitable mean free path lengths. They point out the importance of the crustal waveguide for trapping energy near the surface and that the possibility of energy leakage into the mantle should be taken into account in calculations of seismic albedo.

Bal and Moscoso (2000) explicitly included S-wave polarization and showed that S waves become depolarized under multiple scattering. Yoshimoto (2000) introduced the direct simulation Monte Carlo method, which uses a finite-difference scheme for ray tracing and can thus handle velocity models of arbitrary complexity, including lateral varying structures. However, intrinsic attenuation and directional scattering were not included. Yoshimoto showed that a velocity increase with depth strongly affects the shape of the coda envelope, compared with uniform velocity models, and that it is important to properly model energy that may be trapped at shallow depths.

Margerin et al. (2000) extended the Monte Carlo approach to elastic waves, taking into account P-to-S conversions and S-wave polarization. They considered scattering from randomly distributed spherical inclusions within a homogeneous background material, using the solutions of Wu and Aki (1985a). For both Rayleigh scatterers (spheres much smaller than the seismic wavelength) and Rayleigh–Gans scatterers (spheres comparable to the seismic wavelength), they found good agreement with single-scattering theory at short times and with the diffusion equation solution at long times. In addition, the P-to-S energy density ratio and the coda decay rate at long times converged to their theoretical expected values.

Margerin and Nolet (2003a,b) further extended the Monte Carlo approach to model whole-Earth wave propagation and scattering. They showed that their Monte Carlo synthetics for the PKP AB and BC branches produced energy versus distance results in good agreement with geometric ray theory. They computed scattering properties based on random media models characterized by velocity perturbations with an exponential correlation length. For whole-mantle scattering, they found that the Born approximation is only valid up to mean free paths of about 400 s, corresponding to 0.5% RMS velocity perturbations. They also applied their method to model PKP precursor observations; these results will be discussed later in this chapter.

Shearer and Earle (2004) implemented a particle-based Monte Carlo method for computing whole-Earth scattering. They included both P and S waves radiated from the source, mode conversions, S-wave polarizations, and intrinsic attenuation. For a simple whole-space model, they showed that their approach agreed with theoretical results for the S/P energy ratio and expected t^{-15} falloff in power at large times. For modeling the whole Earth, they included the effects of reflection and transmission coefficients at the free surface, Moho, CMB, and inner-core boundary (ICB). Scattering probabilities and scattering angles were computed assuming random velocity and density variations characterized by an exponential ACF. They applied this method to model the time and distance dependence of high-frequency P coda amplitudes (see **Section 1.24.3.2**).

Wegler et al. (2006), Przybilla et al. (2006), and Przybilla and Korn (2008) compared Monte Carlo solutions using the elastic radiative transfer equations to 3D finite-difference calculations and found good agreement in envelope shapes, including peak amplitudes, envelope broadening, and coda decay rates. However, Przybilla and Korn (2008) documented an interesting breakdown in radiative transfer results based on the Born scattering coefficients in the vicinity of a point source, where waveform modeling shows that even for a pure compressional source, there is some fraction of shear-wave energy generated by near-source scattering that is missed in Born approximation calculations.

All of these results suggest that body-wave scattering in the whole Earth can now be reasonably well modeled using ray theory and particle-based Monte Carlo methods. Although somewhat computationally intensive, continued improvements in computer speed make them practical to run on modest machines. They can handle multiple scattering over a range of scattering intensities, bridging the gap between the Born approximation for weak scattering and the diffusion equation for strong scattering. They also can include general depth-dependent or even 3D variations in scattering properties, including non-isotropic scattering, without a significant increase in computation time compared to simpler problems.

1.24.2.4 Other Theoretical Methods

Lerche and Menke (1986) presented an inversion method to separate intrinsic and scattering attenuation for a plane-layered medium. Gusev (1995) and Gusev and Abubakirov (1999a,b) developed a theory for reconstructing a vertical profile of scattering strength from pulse broadening and delay of the peak amplitude. Saito et al. (2002, 2003) modeled envelope broadening in S waves by applying the parabolic approximation to a von Karman random medium. Sato et al. (2004) extended this approach to develop a hybrid method for synthesizing whole-wave envelopes that uses the envelope obtained from the Markov approximation as a propagator in the radiative transfer integral and showed that the results agreed with finite-difference calculations. Takahashi (2012) also used the Markov approximation to model wide-angle scattering of S waves in northeastern Japan and the time delays in their maximum amplitudes.

The effect of anisotropic random media (where the scattering properties depend upon the angle of the incident wave)

was considered numerically by Wagner and Langston (1992a) and Roth and Korn (1993) and theoretically by Müller and Shapiro (2003), Hong and Wu (2005), and Margerin (2006). Recent work on using small-aperture seismic arrays on coda energy to constrain the directions of individual scatterers includes Schisselé et al. (2004) and Matsumoto (2005).

1.24.3 Scattering Observations

Seismic scattering within the Earth is mainly observed in the incoherent energy that arrives between the direct seismic phases, such as P, S, and PKP. In addition, occasionally specific scatterers can be imaged using seismic arrays. Scattering can also influence the direct phases through amplitude reduction and pulse broadening, effects characterized by the scattering attenuation parameter, Q_{Sc}^{-1}. In this way, studies of seismic attenuation are also resolving scattering, although they often do not attempt to separate intrinsic and scattering attenuation. The incoherent scattered seismic wavefield usually follows a direct seismic arrival and is termed the *coda* of that phase (e.g., P coda and S coda), but occasionally, the ray geometry is such that scattered energy can arrive before a direct phase (e.g., PKP precursors). These precursory arrivals are particularly valuable for studying deep-Earth scattering because they are less sensitive to the strong scattering in the lithosphere. Scattering is usually studied at relatively high frequencies (1 Hz or above) where coda is relatively strong and local earthquake records have their best signal-to-noise ratio.

S-wave coda from local and regional events has been the focus of many studies, has motivated much of the theoretical work, and continues to be an active field of research. Here, I will briefly review S coda studies and their implications for scattering in the crust and lithosphere but will devote more attention to other parts of the scattered seismic wavefield, which provide better constraints on deep-Earth structure. Previous review articles that discuss deep-Earth scattering include Bataille et al. (1990) and Shearer et al. (1998). **Figure 4** shows where much of the scattered energy arrives with respect to travel-time curves for the major seismic phases. In principle, any seismic phase that travels through the lower mantle or the CMB will be sensitive to deep-Earth scattering. Although separating deep scattering effects from crust and lithospheric scattering can be challenging, this is possible in some cases, either

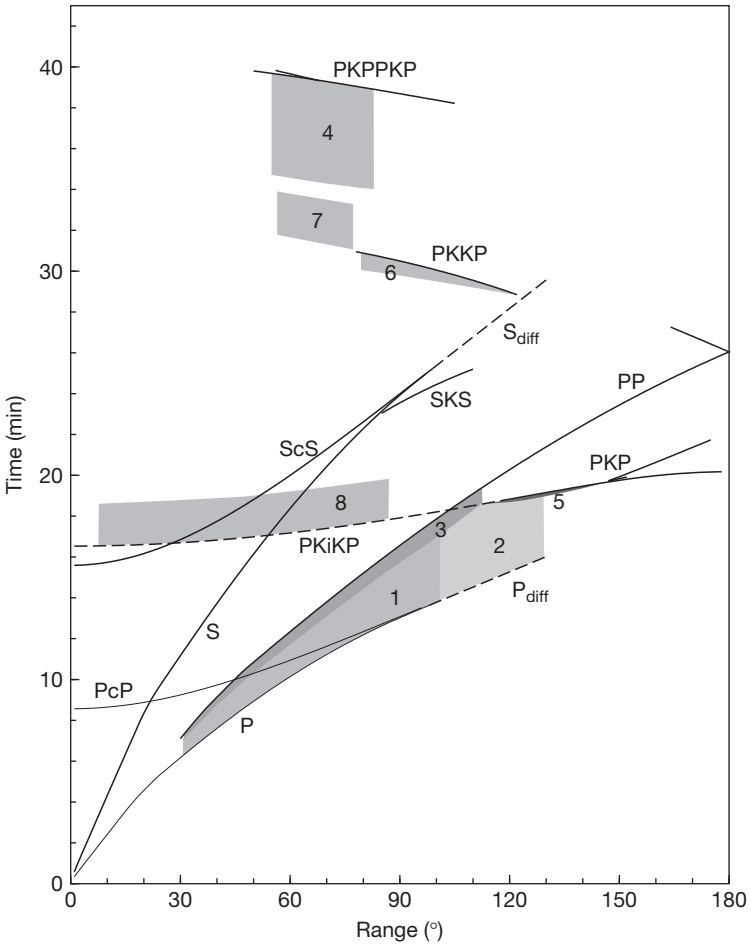

Figure 4 Travel-time curves for teleseismic body waves and some of the regions in the short-period wavefield that contain scattered arrivals. These include (1) P coda, (2) P_{diff} coda, (3) PP precursors, (4) P′P′ precursors, (5) PKP precursors, (6) PKKP precursors, (7) $PKKP_X$, and (8) PKiKP coda. The plotted boundaries are approximate.

from a fortunate ray geometry or by careful comparison of coda amplitudes at different distances or between different phases.

The picture that is emerging from these studies is that seismic scattering from small-scale velocity perturbations is present throughout the Earth, with the exception of the fluid outer core. However, the exact strength, scale length, depth dependence, and lateral variability of the scattering remain unresolved, particularly in the vicinity of the core–mantle and ICBs, where they may also be contributions from topographic irregularities or boundary layer structure.

1.24.3.1 Local and Regional S Coda

S coda measurements are of two main types: (1) those that simply fit the coda decay rate and estimate ${}^{\beta}Q_C$ without attempting to separate scattering and intrinsic attenuation and (2) those that measure energy density and estimate the scattering coefficient g_0 (or its reciprocal, the mean free path). The latter studies typically obtain a separate estimate for intrinsic attenuation and thus can compute the seismic albedo, B_0. The basic relationships among these parameters are given in eqns [4] and [5]. In both types of studies, frequency dependence can also be examined by filtering the data in different bands.

Coda Q studies include Rautian and Khalturin (1978), Roecker et al. (1982), Rodriguez et al. (1983), Singh and Herrmann (1983), Biswas and Aki (1984), Pulli (1984), Rhea (1984), Jin et al. (1985), Del Pezzo et al. (1985), Jin and Aki (1988), van Eck (1988), Kvamme and Havskov (1989), Matsumoto and Hasegawa (1989), Baskoutas and Sato (1989), Oancea et al. (1991), Tsuruga et al. (2003), Giampiccolo et al. (2004), and Goutbeek et al. (2004).

Reviews of Q_C measurements include Herraiz and Espinoa (1987), Matsumoto (1995), and Sato and Fehler (1998, 2012). In general, Q_C is frequency-dependent and increases from about 100 at 1 Hz to 1000 at 20 Hz (i.e., there is less attenuation at higher frequencies). However, there are regional variations of about a factor of ten and typically Q_C is lower in tectonically active areas and higher in stable regions, such as shields. As discussed previously, how to interpret Q_C in terms of Q_{Sc} and Q_I has been the subject of some debate, and it is becoming increasingly clear that depth-dependent calculations (which include variations in the background velocity, the scattering characteristics, and the intrinsic attenuation) are required in many cases to fully describe coda observations.

Some studies (e.g., Akamatsu, 1991; Gagnepain-Beyneix, 1987; Giampiccolo et al., 2004; Goutbeek et al., 2004; Gupta et al., 1998; Kosuga, 1992; Kvamme and Havskov, 1989; Rautian and Khalturin, 1978; Roecker et al., 1982; Singh et al., 2001) have observed that Q_C increases with increasing lapse time (i.e., eqn [1] does not fit the entire coda envelope), suggesting that the later part of the coda contains energy that propagated through less attenuating material than the early part of the coda. Gusev (1995) showed that an increase in Q_C with time in the coda is predicted from a single isotropic scattering model in which Q_{Sc} increases with depth. Margerin et al. (1998) applied radiative transfer theory to show that a model of scattering in the crust above much weaker scattering in the mantle predicts Q_C values that depend upon the reflection coefficient at the Moho, implying that energy leakage into the mantle has implications for the interpretation of coda Q.

Following Sato and Fehler (1998, 2012), we may divide scattering attenuation estimates into those obtained using the single-scattering model and those based on the MLTW analysis. Single-scattering studies include Sato (1978), Aki (1980), Pulli (1984), Dainty et al. (1987), Kosuga (1992), and Baskoutas (1996). Multiple lapse-time studies are summarized in **Figure 5** and include Fehler et al. (1992), Mayeda et al. (1992), Hoshiba (1993), Jin et al. (1994), Akinci et al. (1995), Canas et al. (1998), Ugalde et al. (1998, 2002), Hoshiba et al. (2001), Bianco et al. (2002, 2005), Vargas et al. (2004), Goutbeek et al. (2004), Mukhopadhyay and Tyagi (2008), Badi et al. (2009), Chung et al. (2010), Carcolé and Sato (2010), Lee et al. (2010), and Del Pezzo et al. (2011). Values of the coefficient go for S-to-S scattering range from about 0.002 to 0.05 km^{-1} (mean free paths of 20–500 km) for frequencies between 1 and 30 Hz. Some papers (e.g., Bianco et al., 2005; Goutbeek et al., 2004; Hoshiba, 1993; Jin et al., 1994; Mayeda et al., 1992) have found a frequency dependence in the seismic albedo and among different regions, but in general, this dependence is not as consistent as that seen in Q_C studies. Several recent papers noted the importance of considering depth-dependent velocity structure in computing scattering attenuation (e.g., Bianco et al., 2002, 2005; Hoshiba et al., 2001).

Lacombe et al. (2003) modeled S coda in France at epicentral distances between 100 and 900 km using acoustic radiative transfer theory applied to a two-layer model. They found that a model with scattering confined to the crust and uniform intrinsic attenuation could explain their data at 3 Hz but that the trade-off between scattering and intrinsic attenuation was too strong to reliably determine the relative contribution of each

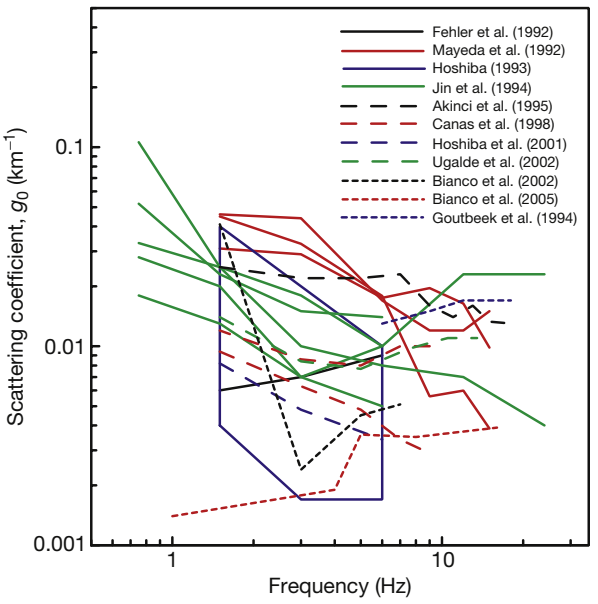

Figure 5 A summary of observations of the total scattering coefficient g_0 for S-wave scattering versus frequency, obtained using the multiple lapse-time window (MLTW) method. Results from various studies around the world are indicated with different colors.

parameter. At the regional epicentral distances of their model, the crustal waveguide had a dominating effect on the S coda.

Carcolé and Sato (2010) applied the MLTW analysis to the over 700 stations of the Japanese Hi-net seismic network to obtain high-resolution maps of both scattering and intrinsic attenuation, which show strong regional variations. In general, northeast Japan has stronger scattering than southwest Japan at 1–2 Hz, with the strongest scattering occurring near the volcanic arcs. In general, scattering and intrinsic attenuation variations are correlated and strong scattering and high intrinsic attenuation are often seen in areas where low seismic velocity anomalies have been observed in other studies. The Carcolé and Sato (2010) results agree reasonably well with the earlier work of Hoshiba (1993) for common stations, but the much greater Hi-net station density permits much more detailed mapping of scattering structure.

In addition to the S coda decay rates at relatively long lapse times used to determine coda Q, there are other aspects of the coda that provide additional constraints on scattering. The complete seismogram envelope can be studied, including the broadening of the direct S envelope and the delay in its peak amplitude (e.g., Obara and Sato, 1995; Sato, 1989, 1991; Scherbaum and Sato, 1991). Deviations from the average coda decay rate for a number of stations can be inverted to construct a 3D model of scattering intensity in the crust and upper mantle (e.g., Chen and Long, 2000; Nishigami, 1991, 1997; Obara, 1997; Taira and Yomogida, 2004). Similar methods were used by Revenaugh (1995, 1999, 2000) to back-project P coda recorded in southern California and by Hedlin and Shearer (2000) to invert PKP precursor amplitudes (see the succeeding text). Periodic rippling of SH coda envelopes in northeastern Japan was noted by Kosuga (1997) who suggested this may be caused by trapped waves within a low-velocity layer in the top part of the subducting slab.

Spudich and Bostwick (1987) showed how Green's function reciprocity can be used to obtain information about the ray takeoff directions from the earthquake source region, using a cluster of earthquakes as a virtual array. Applying this method to aftershocks of the 1984 Morgan Hill earthquake in California, they found that the early S coda was dominated by multiple scattering within 2 km of each seismic station. Scherbaum et al. (1991) used this approach to study two microearthquake clusters in northern Switzerland and found that the early S coda contained energy leaving the source at close to the same angle as the direct wave but that the later (at least 1.5–2 times the S travel time) coda contains energy from waves leaving the source in a variety of directions. Spudich and Miller (1990) and Spudich and Iida (1993) showed how an interpolation approach using distributed earthquake sources can be used to estimate scattering locations in the vicinity of the 1986 North Palm Springs earthquake in California.

Hong and Menke (2008) applied source-array analysis to regional recordings of nuclear explosions at the Balapan test site in Kazakhstan and identified coherent coda energy originating as *Rg* waves that lasts continuously to the end of the coda (more than 700 s) at 0.2–0.8 Hz. This suggests that *Rg*-to-*Rg* scattering is the main contributor to the low-frequency scattered wavefield. However, about 80% of the coda energy is composed of diffusive (multiplied scattered) waves.

1.24.3.2 P Coda

Local and many regional coda studies have mainly focused on the S-wave coda because of its higher amplitude and longer duration than P-wave coda (which is truncated by the S-wave arrival). However, at teleseismic distances, P waves and their coda are more prominent than S waves at high frequencies because of the severe effect of mantle attenuation on the shear waves. A number of studies both from single stations and arrays have attempted to resolve the origin of the scattered waves in the P coda and to distinguish between near-source scattering and near-receiver scattering.

Aki (1973) modeled scattering of P waves beneath the Montana Large Aperture Seismic Array (LASA) using Chernov single-scattering theory. At 0.5 Hz, he achieved a good fit to the data with a random heterogeneity model extending to 60 km depth beneath LASA, with RMS velocity fluctuations of 4% and a correlation distance of 10 km. Stronger scattering at higher frequencies exceeded the validity limits of the Born approximation.

Frankel and Clayton (1986) compared teleseismic travel-time anomalies observed across the LASA and NORSAR, as well as very high-frequency coda ($f \geq 30$ Hz) observed for microearthquakes, to synthetic seismograms for random media generated using a finite-difference method. They found that a random medium with self-similar velocity fluctuations ($a \geq 10$ km) of 5% within an $\sim$100 km thick layer could explain both types of observations.

Dainty (1990) reviewed array studies of teleseismic P coda, such as that recorded by the LASA and NORES arrays. He distinguished between 'coherent' coda, which has nearly the same slowness and back azimuth as direct P, and 'diffuse' coda, which is characterized by energy arriving from many different directions. He argued that coherent coda is generated by shallow, near-source scattering in the crust, rather than deeper in the mantle, because it is absent or weak for deep-focus earthquakes. In contrast, the diffuse coda is produced by near-receiver scattering and has power concentrated at slownesses typical of surface shear waves (Lg). Lay (1987) showed that the dispersive character of the first 15 s of the P coda from nuclear explosions was due to near-source effects.

Gupta and Blandford (1983) and Cessaro and Butler (1987) addressed the question as to how scattering can cause transversely polarized energy to appear in P and P coda, an issue relevant to discrimination methods between earthquakes and explosions. Their observations at different distances and frequency bands suggested that both near-source and near-receiver scattering must be present. Flatté and Wu (1988) performed a statistical analysis of phase and amplitude variations of teleseismic P waves recorded by the NORSAR array. They fitted their results with a two-overlapping-layer model of lithospheric and asthenospheric heterogeneity beneath NORSAR, consisting of the summed contributions from a 0 to 200 km layer with a flat power spectrum and a 15–250 km layer with a k^{-4} power spectrum (the deeper layer corresponds to an exponential autocorrelation model with scale larger than the array aperture of 110 km). The RMS P-velocity variations are 1–4%. This model has relatively more small-scale scatterers in the shallow crust (which the authors attribute to clustered cracks or intrusions) and relatively more large-scale scatterers in the

asthenosphere (which the authors suggest may be temperature or compositional heterogeneities).

Langston (1989) studied teleseismic P waves recorded at station PAS in California and SCP in Pennsylvania. He showed that the coda amplitude cannot be explained by horizontally layered structures of realistic velocity contrasts and that 3D scattering is required. He could explain the observed coda decay by adopting the EFM of Frankel and Wennerberg (1987) for the case of a scattering layer above a homogenous half-space. He found that scattering is more severe at PAS than SCP, as indicated by higher coda levels and a slower decay rate, obtaining a scattering Q estimate for PAS of 239 (2 s period) compared to 582 for SCP.

Korn (1988) examined the P coda from Indonesian earthquakes recorded at the Warramunga array in central Australia and found that the coda energy decreased with increasing source depth. He computed the power in the coda at different frequency bands between 0.75 and 6 Hz and fitted the results with the EFM of Frankel and Wennerberg (1987). The results indicated frequency dependence in both intrinsic attenuation and scattering attenuation ($Q_I = 300$ at 1 Hz, increasing almost linearly with frequency above 1 Hz; $Q_{Sc} = 340$ at 1 Hz, increasing as $f^{0.85}$). Assuming random velocity fluctuations with an exponential ACF, results from Sato (1984) can be used to estimate that RMS velocity variations of 5% at 5.5 km scale length are consistent with the observed Q_{Sc} below the Warramunga array. Korn (1990) extended the EFM to accommodate a scattering layer over a homogeneous half-space (a modeling approach similar to that used by Langston, 1989) and applied the method to the short-period Warramunga array data of Korn (1988) for deep earthquakes. With the new model, he found an average scattering Q of 640 at 1 Hz for the lithosphere below the array and higher values of intrinsic Q, implying that diffusion rather than anelasticity is the dominant factor controlling teleseismic coda decay rates. Korn (1993) further applied this approach to teleseismic *P* coda observations from nine stations around the Pacific. He found significant differences in scattering Q among the stations ($Q_{Sc} = 100$–500). The observed frequency dependence of Q_{Sc} is in approximate agreement with single-scattering theory for random heterogeneities and favors von Karman type ACFs over Gaussian or self-similar models.

Bannister et al. (1990) analyzed teleseismic P coda recorded at the NORES array using both array and three-component methods. They resolved both near-source and near-receiver scattering contributions to coda, with the bulk of receiver-side scattering resulting from P-to-*Rg* conversions from two nearby areas (10 and 30 km away) with significant topography. Gupta et al. (1990) performed frequency–wave number analysis on high-frequency NORES data and identified both near-receiver P-to-*Rg* scattering and near-source *Rg*-to-P scattering. Dainty and Toksöz (1990) examined scattering in regional seismograms recorded by the NORES, FINES, and ARCES arrays. P coda energy was concentrated in the on-azimuth direction but appeared at different phase velocities, suggesting different contribution mechanisms.

Wagner and Langston (1992b) applied frequency–wave number analysis to P′P′ (PKPPKP) waves recorded by the NORES arrays for deep earthquakes. Most of the coda was vertically propagating, but an arrival about 15 s after the direct wave can be identified as body-to-Rayleigh-wave scattering from a point 30 km west-southwest of the array (this scattering location was previously identified in P-wave coda by Bannister et al. (1990) and Gupta et al. (1990). Revenaugh (1995, 1999, 2000) applied a Kirchhoff migration approach to back-project P coda recorded in southern California to image lateral variations in scattering intensity within the crust and identified correlations between scattering strength and the locations of faults and other tectonic features. Frederiksen and Revenaugh (2004) applied Born scattering theory to teleseismic P coda to invert for variations in scattering strength near faults in southern California.

Neele and Snieder (1991) used the NARS and GRF arrays in Europe to study long-period teleseismic P coda and found it to be coherent with energy arriving from the source azimuth. They concluded that long-period P coda does not contain a significant amount of scattered energy and can be explained with spherically symmetrical models and is particularly sensitive to structure in upper-mantle low-velocity zones. Ritter et al. (1997, 1998) studied the frequency dependence of teleseismic P coda recorded in the French Massif Central, which they modeled as a 70 km thick layer with velocity fluctuations of 3–7% and heterogeneity scale lengths of 1–16 km. Rothert and Ritter (2000) studied P coda in intermediate-depth Hindu Kush earthquakes recorded at the GRF array in Germany about 44° away. They applied a method based on the theory of Shapiro and Kneig (1993) and Shapiro et al. (1996) and found that the observed wavefield fluctuations are consistent with random crustal heterogeneities of 3–7% and isotropic correlation lengths of 0.6–4.8 km. Ritter and Rothert (2000) used a similar approach on teleseismic P coda to infer differences in scattering strength beneath two local networks in Europe. Hock et al. (2000, 2004) used teleseismic P coda to characterize random lithospheric heterogeneities across Europe using the EFM. They obtained a range of different scale lengths and RMS velocity fluctuations on the order to 3–8%. Nishimura et al. (2002) analyzed transverse components in teleseismic P coda for stations in the western Pacific and noted stronger scattering for stations close to plate boundaries compared to those on stable continents.

In some cases, analysis of P coda can reveal individual scatterers and/or discontinuities at midmantle depths below subduction zone earthquakes (Castle and Creager, 1999; Kaneshima, 2003, 2009; Kaneshima and Helffrich, 1998, 1999, 2003, 2009, 2010; Krüger et al., 2001; Niu and Kawakatsu, 1994, 1997). Other individual scatterers (or regions of strong scattering) have been observed near the CMB from PcP precursors (Brana and Helffrich, 2004; Scherbaum et al., 1997; Weber and Davis, 1990; Weber and Kornig, 1990) and PKP precursors (Thomas et al., 1999; Vidale and Hedlin, 1998).

Shearer and Earle (2004) attempted to systematically characterize and model globally averaged short-period teleseismic P coda from both shallow and deep earthquakes. This was the first attempt to fit a global data set of P-wave amplitudes and coda energy levels with a comprehensive energy-preserving model that specified scattering and intrinsic attenuation throughout the Earth. Examining global seismic network (GSN) data between 1990 and 1999 at source–receiver distances between 10° and 100°, they identified high signal-to-noise records and stacked over 7500 traces from shallow

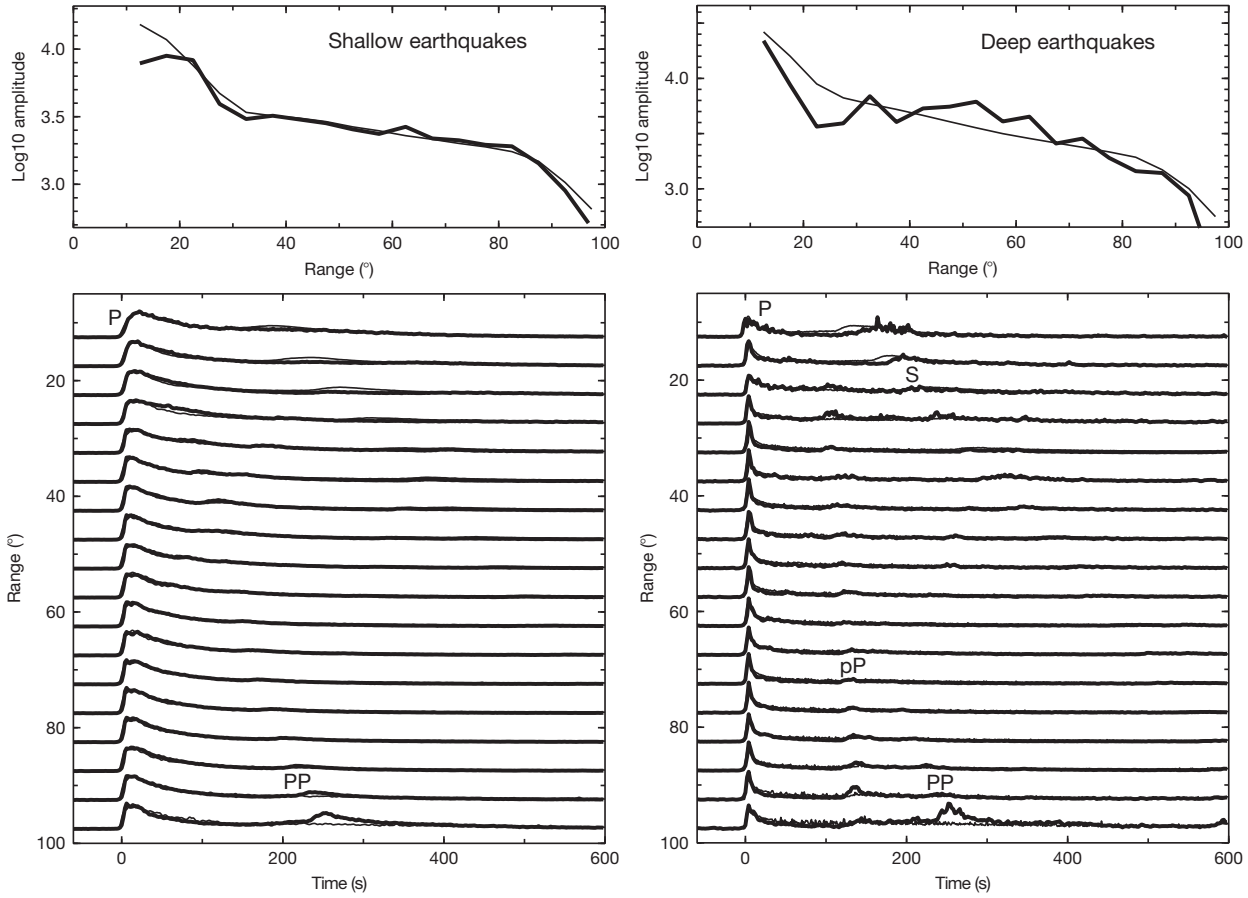

Figure 6 Comparisons between envelope function stacks of teleseismic P-wave arrivals (solid lines) with predictions of a Monte Carlo simulation for a whole-Earth scattering model (thin lines) as obtained by Shearer and Earle (2004). The left panels show results for shallow earthquakes ($\leq$50 km); the right panels are for deep earthquakes ($\geq$400 km). The top panels show peak P-wave amplitude versus epicentral distance. The bottom panels show coda envelopes in 5° distance bins plotted as a function of time from the direct P arrivals, with amplitudes normalized to the same energy in the first 30 s.

events (depth $\leq$ 50 km) and over 650 traces from deep events (depth $\geq$400 km). The stacking method involved summing envelope functions from 0.5 to 2.5 Hz band-pass-filtered traces, normalized to the maximum P amplitude. Peak P amplitudes were separately processed so that absolute P amplitude versus source–receiver distance information was preserved. The coda shape was markedly different between the shallow and deep-event stacks (see **Figure 6**). The shallow earthquake coda was much more energetic and long-lasting than the deep-event coda, indicating that the bulk of the teleseismic P coda from shallow events is caused by near-source scattering above 600 km depth.

Shearer and Earle modeled these observations using a Monte Carlo, particle-based approach (see above) in which millions of seismic phonons are randomly sprayed from the source and tracked through the Earth. They found that most scattering occurs in the lithosphere and upper mantle, as previous results had indicated, but that some lower-mantle scattering was also required to achieve the best fits to the data. Their preferred exponential autocorrelation random heterogeneity model contained 4% RMS velocity heterogeneity at 4 km scale length from the surface to 200 km depth, 3% heterogeneity at 4 km scale between 200 and 600 km, and 0.5% heterogeneity at 8 km scale length between 600 km and the CMB. They assumed equal and correlated P and S fractional velocity perturbations and a density/velocity scaling ratio of 0.8. Intrinsic attenuation was ${}^{\alpha}Q_I = 450$ above 200 km and ${}^{\alpha}Q_I = 2500$ below 200 km, with ${}^{\beta}Q_I = (4/9)\ {}^{\alpha}Q_I$ (an approximation that assumes all the attenuation is in shear). This model produced a reasonable overall fit, for both the shallow and deep-event observations, of the amplitude decay with epicentral distance of the peak P amplitude and the P coda amplitude and duration (see **Figure 6**). These numbers imply that for both P and S waves, the seismic albedo, B_0, is about 75–90% in the upper mantle above 600 km and about 25–35% in the lower mantle, consistent with the total attenuation being dominated by scattering in the upper mantle and by intrinsic energy loss in the lower mantle.

The 4% velocity perturbations for the uppermost layer in the Shearer and Earle (2004) model are in rough agreement with previous P coda analyses by Frankel and Clayton (1986), Flatté and Wu (1988), and Korn (1988); and the S-wave mean

free path of 50 km for the upper 200 km is within the range of mean free paths estimated from regional measurements of lithospheric scattering. However, limitations of the Shearer and Earle (2004) study include the restriction to single-station, vertical-component data (i.e., wave polarization, slowness, and azimuth constraints from three-component and/or array analyses are not used) and a single frequency band near 1 Hz. In addition, the ray theoretical approach cannot properly account for body-to-surface-wave-converted energy, which some array studies suggest are an important component of P coda. In addition, the Shearer and Earle (2004) models are for globally averaged P coda stacks. Later, Shearer and Earle (2008) showed that separating P coda stacks by source and receiver locations reveals significant variations, indicating lateral variations in scattering strength.

Resolving possible lower-mantle scattering using P coda is difficult because of the much stronger scattering from shallow structure. However, Shearer and Earle (2004) found that ~0.5% RMS velocity heterogeneity in the lower mantle was required to achieve the best fit to P coda amplitudes at epicentral distances beyond 50°. This value is substantially more than the estimates for lower-mantle velocity perturbations derived from PKP precursors of 0.1–0.2% from Margerin and Nolet (2003b) and 0.1% from Mancinelli and Shearer (2013).

1.24.3.3 P_n Coda

A prominent feature of long-range records of nuclear explosions across Eurasia is P_n and its coda, which can be observed to distances of more than 3000 km (e.g., Morozov et al., 1998; Ryberg et al., 1995, 2000). As discussed by Nielsen and Thybo (2003), there are two main models for upper-mantle structure that have been proposed to explain these observations: (1) Ryberg et al. (1995, 2000) and Tittgemeyer et al. (1996) proposed random velocity fluctuations between the Moho and about 140 km depth in which the vertical correlation length (0.5 km) is much smaller than the horizontal correlation length (20 km). These fluctuations cause multiple scattering that form a waveguide that can propagate high-frequency P_n to long distances. (2) Morozov et al. (1998), Morozov and Smithson (2000), Nielsen et al. (2003b), and Nielsen and Thybo (2006) favored a model in which P_n is a whispering gallery phase traveling as multiple underside reflections off the Moho, with the coda generated by crustal scattering. Nielsen and Thybo's (2003) preferred model has random crustal velocity perturbations between 15 and 40 km depth with a vertical correlation length of 0.6 km and a horizontal correlation length of 2.4 km. However, Nielsen et al. (2003a) found that the scattered arrivals seen at 800–1400 km distance for profile 'Kraton' required scattering within a layer between about 100 and 185 km depth and could be modeled with 2D finite-difference synthetics assuming 2% RMS velocity variations.

An important aspect of all these models is that their random velocity perturbations are horizontally elongated (i.e., anisotropic). At least for the lower crust, there is also some evidence for this from reflection seismic profiles (e.g., Holliger and Levander, 1992; Wenzel et al., 1987). This contrasts with most modeling of S and P coda, which typically assumes isotropic random heterogeneity.

1.24.3.4 P_{diff} Coda

Another phase particularly sensitive to deep-Earth scattering is P_{diff} and its coda. P_{diff} contains P energy diffracted around the CMB and is observed at distances >98°. The direct phase is seen most clearly at long periods, but high-frequency (~1 Hz) P_{diff} and its coda can be detected to beyond 130° (e.g., Earle and Shearer, 2001). P_{diff} coda is a typically emergent wave train that decays slowly enough that it can commonly be observed for several minutes until it is obscured by the PP and PKP arrivals. Husebye and Madariaga (1970) concluded that P_{diff} coda (which they termed P(diff) tail) could not be explained as simple P diffraction at the CMB or by reflections from the core and suggested that it originated from reflections or multiple paths in the upper mantle (similar to the proposed explanation for PP precursors given by Bolt et al., 1968). However, later work has shown this to be unlikely, given the large differences seen between observations of deep-turning direct P coda and P_{diff} coda. Bataille et al. (1990) reviewed previous studies of P_{diff} coda and suggested that it is caused by multiple scattering near the CMB, with propagation to long distances possibly enhanced by the presence of a low-velocity layer within D″.

Tono and Yomogida (1996) examined P_{diff} coda in 15 short-period records from deep earthquakes at distances of 103°–120° and found considerable variation in the appearance and duration of P_{diff} coda. Comparisons between P_{diff} and direct P waves at shorter distances, as well as particle motion analysis of P_{diff} coda, indicated that the coda was caused by deep-Earth scattering. Tono and Yomogida computed synthetics using the boundary integral method of Benites et al. (1992), applied to a simplified model of an incident wave grazing an irregular CMB. They were able to fit a subset of their observations in which the P_{diff} coda duration was relatively short (<50 s), with bumps on the CMB with minimum heights of 5–40 km. Such large CMB topography is unrealistic given PcP studies, which have indicated a relatively flat and smooth CMB (e.g., Kampfmann and Muüller, 1989; Vidale and Benz, 1992), and PKKP precursor observations that limit CMB RMS topography to <315 m at 10 km wavelength (Earle and Shearer, 1997, see in the succeeding text), but it is likely that volumetric heterogeneity within *D″* could produce similar scattering. Although the Tono and Yomogida (1996) model included multiple scattering, they could not fit the long tail (>50 s) of some of their P_{diff} observations, and they suggested that for such cases, a low-velocity zone just above the CMB is channeling the scattered energy. Strong heterogeneity and low-velocity zones of varying thicknesses have been observed above the CMB (e.g., see review by Garnero, 2000, and Lay, this volume), but it is not yet clear if these models can explain P_{diff} observations.

Bataille and Lund (1996) argued for a deep origin for P_{diff} coda by comparing coda shapes for P near 90° range and P_{diff} at 102°–105°. The P_{diff} coda is more emergent and lasts much longer than the direct P coda. This argues against a shallow source for the coda because this would produce roughly the same effect on both P and P_{diff}. Baitaille and Lund found that their observed coda decay rate for a single P_{diff} observation at 116° could be fitted with a model of multiple scattering within a 2D shell at the CMB. Tono and Yomogida (1997) examined P_{diff} in records of the 1994 Bolivian deep earthquake at

epicentral distances of 100°–122°. They analyzed both global broadband stations and short-period network stations from New Zealand. They found that short-period energy continued to arrive for over 100 s after P_{diff} itself, more than twice as long as the estimated source duration of the mainshock. Comparisons between the coda decay rate of P_{diff} with other phases, as well as polarization analysis, indicated a deep origin for P_{diff} coda.

Earle and Shearer (2001) stacked 924 high-quality, short-period seismograms from shallow events at source–receiver distances between 92.5° and 132.5° to obtain average P and P_{diff} coda shapes. The results confirm the Bataille and Lund (1996) observation that P coda changes in character near 100°. In particular, P_{diff} becomes increasingly extended and emergent at longer distances. Its peak amplitude also diminishes with increasing distance, but P_{diff} can still be observed in the stacks at 130°. Earle and Shearer also performed a polarization stack (Earle, 1999), which showed that the polarization of P_{diff} coda is similar to P_{diff} (see **Figure 7**). To model these results, Earle and Shearer (2001) applied single-scattering theory for

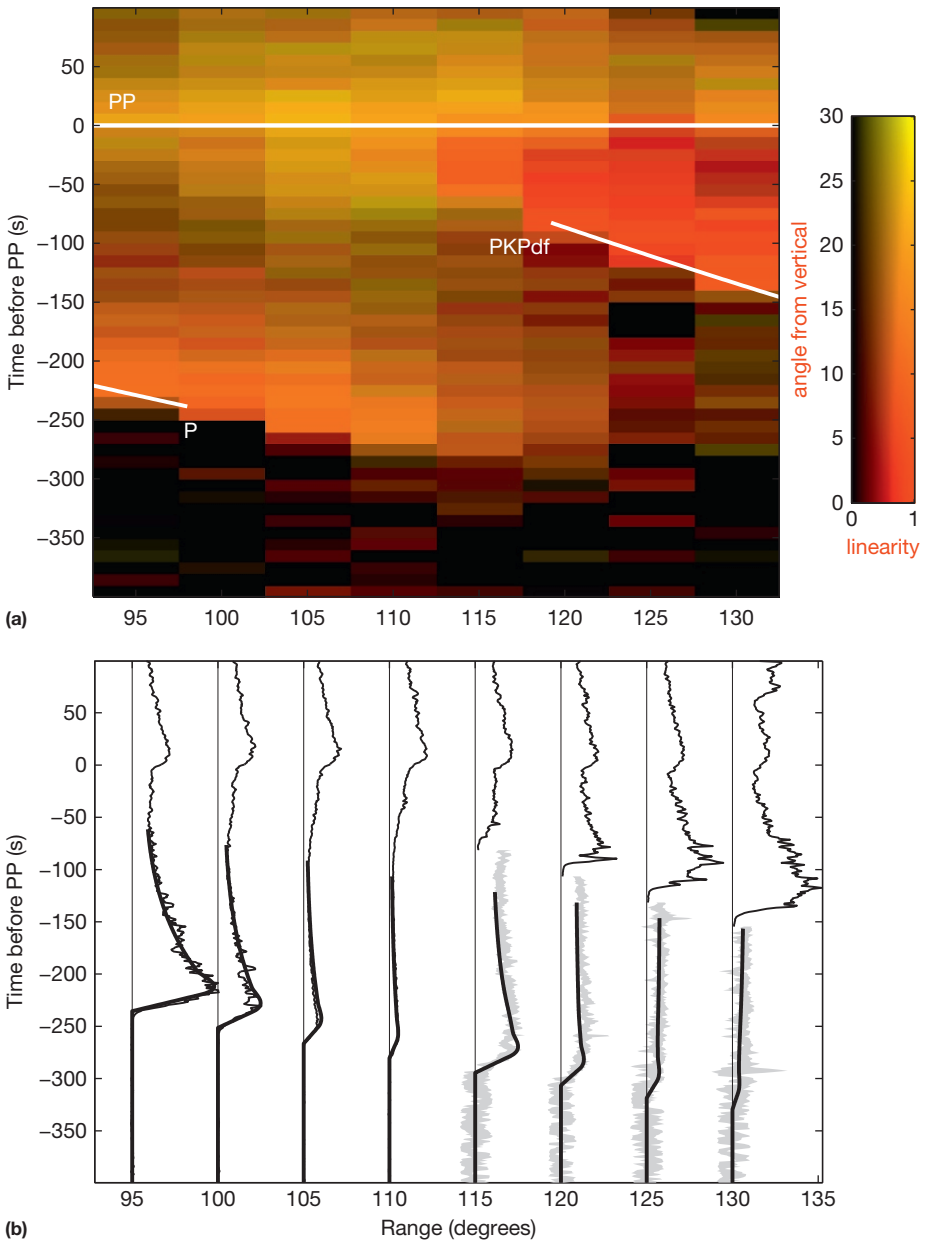

Figure 7 Global seismogram stacks and scattering model predictions for high-frequency P_{diff} from Earle and Shearer (2001). (a) A stacked image of P_{diff} polarization and linearity. Times are relative to the theoretical PP arrival times, and direct P and PKP(DF) are also shown. (b) An amplitude stack of P_{diff} envelopes (wiggly lines) compared to model predictions (smooth lines) for a uniform mantle scattering model. Amplitudes are normalized to the maximum PP amplitude. To better show the small-amplitude P_{diff} arrivals, the traces are magnified by 10 for times 20 s before PKP at distances $>112.5°$. The width of the magnified data traces is equal to the two-sigma error in the data stack, estimated using a bootstrap method.

evenly distributed scatterers throughout the mantle. The resulting synthetics included P-to-P, P_{diff}-to-P, and P-to-P_{diff} scattering paths. They applied a hybrid scheme that used reflectivity to compute deep-turning P and P_{diff} amplitudes and ray theory for the shallower turning rays. Scattering was computed assuming a random medium model with an exponential ACF. Synthetics generated for a scale length of 2 km and 1% RMS velocity variations achieved a good fit to the amplitude and shape of P and P_{diff} coda and a reasonable fit to the polarization angles. Thus, a fairly modest level of whole-mantle scattering appears sufficient to explain the main features in P_{diff} observations, although Earle and Shearer could not exclude the possibility that multiple-scattering models could achieve similar fits. More recently, Rost et al. (2006) stacked short-period seismograms from the GSNs and noticed that almost no short-period P_{diff} is detectable at distances larger than 108°. They suggested that this abrupt disappearance of high-frequency P_{diff} is caused by strong heterogeneity and scattering at the CMB.

1.24.3.5 PP and P′P′ Precursors

The decay in short-period coda amplitude with time following direct P and P_{diff} stops and amplitudes begin to increase some time before the surface-reflected PP phase at distances less than about 110° (at longer distances PKP intercedes). This energy is typically incoherent but sometimes forms distinct arrivals; both are termed PP precursors. Early explanations for PP precursor observations involved topside and bottomside reflections off discontinuities in the upper mantle (Bolt, 1970; Bolt et al., 1968; Gutowski and Kanasewich, 1974; Husebye and Madariaga, 1970; Nguyen-Hai, 1963). It is now recognized that such arrivals do exist and form globally coherent seismic phases that can readily be observed at long periods (e.g., Shearer, 1990, 1991). In particular, the 410 and 660 km discontinuities create discrete topside reflections that follow direct P by about 1.5–2.5 min and underside reflections that proceed PP by similar time offsets. However, the high-frequency PP precursor wavefield is much more continuous, and it is difficult to identify discrete arrivals from upper-mantle discontinuities, although Wajeman (1988) was able to identify underside P reflections from discontinuities at 300 and 670 km depth by stacking broadband data from the NARS array in Europe. Wright and Muirhead (1969) and Wright (1972) used array studies to show that PP precursors often have slownesses that are significantly less than or greater than that expected for underside reflections beneath the PP bouncepoint, which is consistent with asymmetrical reflections at distances near 20° from either the source or the receiver. However, this explanation does not explain the generally continuous nature of the PP precursor wavefield. The currently accepted explanation for the bulk of the PP precursor energy involves scattering from the near-surface and was first proposed by Cleary et al. (1975) and King et al. (1975). Cleary et al. (1975) proposed that PP precursors result from scattering by heterogeneities within and near the crust, as evidenced by travel-time and slowness observations of two Novaya Zemlya explosions recorded by the Warramunga array in Australia. King et al. (1975) modeled PP precursor observations from the Warramunga array and NORSAR using Born single-scattering theory. They assumed 1% RMS variations in elastic properties and a Gaussian autocorrelation model with a 12 km scale length within the uppermost 100 km of the crust and upper mantle. This model successfully predicted the onset times, duration, and slowness of the observed PP precursors but underpredicted the precursor amplitudes, suggesting that stronger scattering, perhaps too large for single-scattering theory, would be required to fully explain the observations. King et al. noted that the focusing of energy at 20° distance by the mantle transition zone could explain the high and low slowness observations of their study and of Wright (1972).

More recently, Rost et al. (2008) studied PP precursors recorded by the Yellowknife array in Canada and used both slowness, back azimuth, and travel-time information to locate mantle scatterers between the surface and about 1000 km depth. Scattering locations below Tonga and the Marianas are consistent with the positions of subducted slabs and the presence of small-scale velocity contrasts from the chemically distinct old oceanic crust penetrating well below 660 km depth.

A related discussion has concerned precursors to PKPPKP (or P′P′), for which the main phase also has an underside reflection near the midpoint between source and receiver. In this case, however, short-period reflections from the 410 and 660 km discontinuities are much easier to observe, and this has become one of the best constraints on the sharpness of these features (e.g., Benz and Vidale, 1993; Davis et al., 1989; Engdahl and Flinn, 1969; Richards, 1972; Xu et al., 2003). However, these reflections arrive 90–150 s before P′P′ and cannot explain the later parts of the precursor wave train. Whitcomb (1973) suggested they were asymmetrical reflections at sloping interfaces, a mechanism similar to that proposed by Wright and Muirhead (1969) and Wright (1972) for PP precursors. King and Cleary (1974) proposed that near-surface scattering near the P′P′ bouncepoint could explain the extended duration and emergent nature of P′P′ precursors. Vinnik (1981) used single-scattering theory to model globally averaged P′P′ precursor amplitudes at three different time intervals and obtained a good fit with a Gaussian ACF of 13 km scale length with RMS velocity perturbations in the lithosphere of about 1.6%.

More recently, Tkalčić et al. (2006) observed P′P′ precursors at epicentral distances $< 10°$, which they interpret as backscattering from small-scale heterogeneities at 150–220 km depth beneath the P′P′ bouncepoints because array studies show that the precursors have the same slowness as the direct phase. Earle et al. (2011) reported and studied P′P′ precursors at 1 Hz between 30° and 50° epicentral distance. Beamforming of data from the LASA array in Montana showed that the arrivals likely result from off-azimuth scattering of PKPbc to PKPbc in the crust and upper mantle. The Earle et al. LASA observations can be approximately fitted with scattering confined to the uppermost 200 km of the crust and mantle, but the scattering geometry should in principle be able to place bounds on scattering strength throughout the entire depth range of the mantle and thus provide a useful complement to PKP precursor studies, which are sensitive only to the lowermost mantle. Wu et al. (2012) also studied high-frequency P′P′ precursors, both using global seismic stations and the Yellowknife and Warramunga arrays, obtaining results that supported the Earle et al. (2011) model of asymmetrical scattering as being the main cause of the precursor energy.

1.24.3.6 PKP Precursors

Perhaps the most direct evidence for deep-Earth scattering comes from observations of precursors to the core phase PKP. They were first noted by Gutenberg and Richter (1934). The precursors are seen at source–receiver distances between about 120° and 145° and precede PKP by up to ~20 s. They are observed most readily at high frequencies and are usually emergent in character and stronger at longer distances. Older, and now discredited, hypotheses for their origin include refraction in the inner core (Gutenberg, 1957), diffraction of PKP from the CMB (Bullen and Burke-Gaffney, 1958; Doornbos and Husebye, 1972), and refraction or reflection of PKP at transition layers between the inner and outer cores (Bolt, 1962; Sacks and Saa, 1969). However, it is now understood that PKP precursors are not caused by radially symmetrical structures but result from scattering from small-scale heterogeneity at the CMB or within the lowermost mantle (Cleary and Haddon, 1972; Haddon, 1972). This scattering diverts energy from the primary PKP ray paths, permitting waves from the AB and BC branches to arrive at shorter source–receiver distances than the B caustic near 145° and earlier than the direct PKP(DF) phase. It should be noted that although the PKP precursors arrive in front of PKP(DF), they result from scattering from different PKP branches. Scattered energy from PKP(DF) itself contributes only to the coda following PKP(DF), not to the precursor wavefield. In addition, the scattering region must be deep to create the precursors. Scattering of PKP(BC) from the shallow mantle will not produce precursors at the observed times and distances. Thus, deep-Earth scattering can be observed uncontaminated by the stronger scattering that occurs in the crust and upper mantle. This unique ray geometry, which results from the velocity drop between the mantle and the outer core, makes PKP precursors invaluable for characterizing small-scale heterogeneity near the CMB.

The interpretation of PKP precursors in terms of scattering was first detailed by Haddon (1972) and Cleary and Haddon (1972). The primary evidence in favor of this model is the good agreement between the observed and theoretical onset times of the precursor wave train for scattering at the CMB. However, analyses from seismic arrays (e.g., Davies and Husebye, 1972; Doornbos, 1976; Doornbos and Husebye, 1972; Doornbos and Vlaar, 1973; Husebye et al., 1976; King et al., 1973, 1974) also showed that the travel times and incidence angles of the precursors were consistent with the scattering theory. Haddon and Cleary (1974) used Chernov scattering theory to show that the precursor amplitudes could be explained with 1% random velocity heterogeneity with a correlation length of 30 km in a 200 km thick layer in the lowermost mantle just above the CMB. In contrast, Doornbos and Vlaar (1973) and Doornbos (1976) argued that the scattering region extends to 600–900 km above the CMB and calculated (using the Knopoff and Hudson, 1964, single-scattering theory) that much larger velocity anomalies must be present. Later, however, Doornbos (1978) used perturbation theory to show that short-wavelength CMB topography could also explain the observations (see also Haddon, 1982), as had previously been suggested by Haddon and Cleary (1974). Bataille and Flatté (1988) concluded that their observations of 130 PKP precursor records could be explained equally well by 0.5–1% RMS velocity perturbations in a 200 km thick layer at the base of the mantle or by CMB topography with RMS height of ~300 m (see also Bataille et al., 1990).

One difficulty in comparing results among these older PKP precursor studies is that it is not clear how many of their differences are due to differences in observations (i.e., the selection of precursor waveforms they examine) compared to differences in theory or modeling assumptions. PKP precursor amplitudes are quite variable, and it is likely that studies that focus on the clearest observations will be biased (at least in terms of determining globally averaged Earth properties) by using many records with anomalously large amplitudes. To obtain a clearer global picture of average PKP precursor behavior, Hedlin et al. (1997) stacked envelope functions from 1600 high signal-to-noise PKP waveforms at distances between 118° and 145° (see **Figure 8**). They included all records, regardless of whether precursors could be observed, to avoid biasing their estimates of average precursor amplitudes. In this way, they obtained the first comprehensive image of the precursor wavefield and found that precursor amplitude grows with both distance and time. The growth in average precursor amplitude with time continues steadily until the direct PKP(DF) arrival; no maximum amplitude peak is seen prior to PKP(DF) as had been suggested by Doornbos and Husebye (1972). This is the fundamental observation that led Hedlin et al. (1997) to conclude that scattering is not confined to the immediate vicinity of the CMB but must extend for some distance into the mantle.

Hedlin et al. (1997) and Shearer et al. (1998) modeled these observations using single-scattering theory for a random medium characterized with an exponential ACF. They found that the best overall fit to the observations was provided with ~1% RMS velocity heterogeneity (this value was later found to be erroneously large owing to a programming bug, see below) at 8 km scale length extending throughout the lower mantle, although fits almost as good could be obtained for 4 and 12 km scale lengths. Similar fits could also be achieved with a Gaussian ACF using a slightly lower RMS velocity heterogeneity. To explain the steady increase in precursor amplitude with time, these models contained uniform heterogeneity throughout the lower mantle, and Hedlin et al. (1997) argued that the data require the scattering to extend at least 1000 km above the CMB and that there is no indication for a significant concentration of the scattering near the CMB. This conclusion was supported by Cormier (1999), who tested both isotropic and anisotropic distributions of scale lengths and found that the PKP precursor envelope shapes are consistent with dominantly isotropic 1% fluctuations in P velocity in the 0.05–0.5 km^{-1} wave number band (i.e., 12–120 km wavelengths).

Most modeling of PKP precursors has used single-scattering theory and the Born approximation. The validity of this approximation for mantle scattering was questioned by Hudson and Heritage (1981). However, Doornbos (1988) found similar results from single- versus multiple-scattering theory for CMB topography of several hundred meters (i.e., the amount proposed by Doornbos, 1978, to explain PKP precursor observations), and Cormier (1995) found the Born approximation to be valid for modeling distributed heterogeneity in the D'' region when compared to results from the higher-order theory of Korneev and Johnson (1993a,b). More recently,

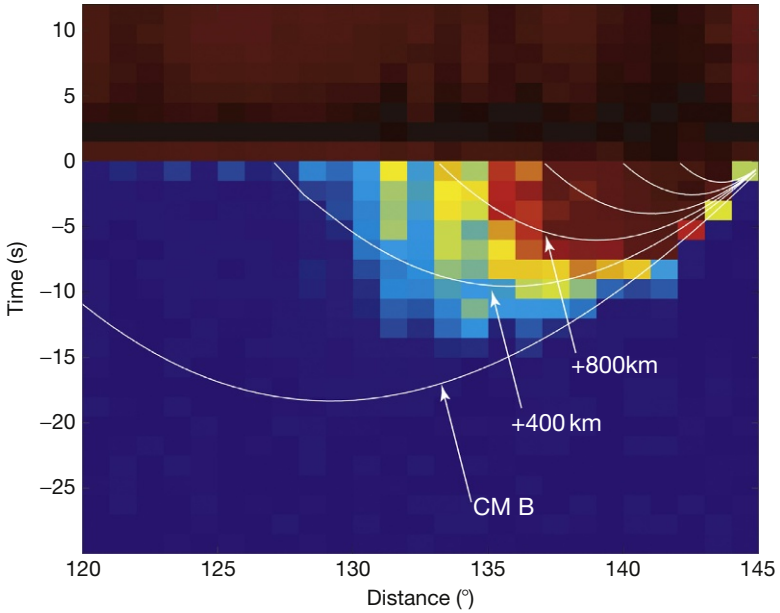

Figure 8 PKP precursors as imaged by stacking 1600 short-period seismograms by Hedlin et al. (1997). The colors indicate the strength of the precursors, ranging from dark blue (zero amplitude) to green, yellow, red, and brown (highest amplitudes). The onset of PKP(DF) is shown by the edge of the brown region at zero time. The precursors exhibit increasing amplitude with both distance and time. The white curves show the theoretical precursor onset times for scattering at 400 km depth intervals above the core–mantle boundary (CMB).

Margerin and Nolet (2003a,b) modeled PKP precursors using radiative transfer theory and a Monte Carlo method (see the preceding text). Their results supported Hedlin et al. (1997) and Shearer et al. (1998) in finding that whole-mantle scattering fit the data better than scattering restricted to near the CMB, but they obtained much smaller P-velocity perturbations of 0.1–0.2% versus the 1% originally proposed by Hedlin et al. The accuracy of the Margerin and Nolet result for the velocity perturbations was recently confirmed by Mancinelli and Shearer (2013), who used a multiple-scattering Monte Carlo method to show that updated PKP precursor stacks could be fit with 0.1% RMS velocity perturbations. They found that similar results could be obtained using Born theory and that the 1% value in the older Hedlin et al. work was due to a programming mistake. Margerin and Nolet showed that the Born approximation is accurate for whole-mantle scattering models only when the velocity heterogeneity is $< 0.5\%$. Finally, they concluded that exponential correlation length models do not fit the distance dependence in PKP precursor amplitudes as well as models containing more small-scale structure.

The steady increase in amplitude with time in PKP precursor stacks requires that globally averaged small-scale mantle heterogeneity extends above the lowermost few hundred kilometers of the mantle. However, determining exactly how far the scattering must extend above the CMB is a challenging problem because only a small fraction of the precursor wavefield is sensitive to scattering above 600 km from the CMB, and this fraction continues to shrink for shallower scattering depths. For example, at 1200 km above the CMB, precursors are produced only between 138° and 145° and arrive at most 3 s before PKP(DF) (see **Figure 8**). Separating the amplitude contribution from these arrivals from that produced by scattering at deeper depths in the mantle is very difficult, particularly when the pulse broadening caused by realistic source-time functions and shallow scattering and reverberations are taken into account. An alternative approach to constraining the strength of midmantle scattering is to examine the scattered PKP wavefield after the direct PKP(DF) arrival (Hedlin and Shearer, 2002). This is comprised of a sum of PKP(DF) coda and scattered PKP(AB) and PKP(BC) energy. In principle, if the contribution from the PKP(DF) coda could be removed, the remaining scattered wavefield would provide improved constraints on the strength of midmantle scattering. However, Hedlin and Shearer (2002) found that this approach did not provide improved depth resolution of mantle scattering compared to previous analyses of PKP precursors, owing at least in part to relatively large scatter in coda amplitudes as constrained by a data resampling analysis. Their results were, however, consistent with uniform mantle scattering with 1% RMS random velocity perturbations at 8 km scale length.

The preceding discussion considered only average PKP precursor properties and models with radial variations in scattering. However, PKP precursor amplitudes are quite variable, as noted by Bataille and Flatté (1988) and Bataille et al. (1990), suggesting lateral variations in scattering strength. Vidale and Hedlin (1998) identified anomalously strong PKP precursors for ray paths that indicated intense scattering at the CMB beneath Tonga. Wen and Helmberger (1998) observed broadband PKP precursors from near the same region, which they modeled as Gaussian-shaped ultra-low-velocity zones of 60–80 km height with P-velocity drops of 7% or more over 100–300 km (to account for the long-period part of the precursors), superimposed on smaller-scale anomalies to explain the high-frequency part of the precursors.

Array analyses can resolve the source–receiver ambiguity of PKP scattering and often permit location of individual

scatterers or regions of strong scattering in the lower mantle. Thomas et al. (1999) used German network and array records of PKP precursors to identify isolated scatterers in the lower mantle. Niu and Wen (2001) identified strong PKP precursors for South American earthquakes recorded by the Jarray in Japan, which they modeled with 6% velocity perturbations within a 100 km thick layer just above the CMB in a 200 km by 300 km area west of Mexico. Cao and Romanowicz (2007) used Canadian Yellowknife array records of an earthquake doublet to identify receiver-side scatterers at depths ranging from 0 to 600 km above the CMB and scattering angles between 16° and 46°. They found that the scatterer locations suggest they may be fragments of fossil slabs from ancient subduction under North America. Miller and Niu (2008) used data from Caribbean arrays to image strong scatterers near the CMB, which are surrounded by high-velocity anomalies associated with the Farallon slab, and suggested a segregation mechanism that could concentrate the scatterers into a localized region. Thomas et al. (2009) examined South Pacific earthquakes recorded by German and Ethiopian arrays and studied both PKP precursors (seen for both arrays) and the amplitude of diffractions from the PKP b caustic (anomalously large for the Ethiopian data). They found that low-velocity regions just above the CMB could act as waveguides to produce large PKP b-diffractions but that these low-velocity regions must also contain small-scale heterogeneities to explain the high-frequency scattering seen in the data. They proposed that melt inclusions could explain both the lower velocities seen at long wavelengths and produce the scattering observed at short wavelengths.

Hedlin and Shearer (2000) attempted to systematically map lateral variations in scattering strength using a global set of high-quality PKP precursor records. Their analysis was complicated by the limited volume sampled by each source–receiver pair, the ambiguity between source- and receiver-side scattering, and the sparse and uneven data coverage. However, they were able to identify some large-scale variations in scattering strength that were robust with respect to data resampling tests. These include stronger than average scattering beneath Central Africa, parts of North America, and just north of India and weaker than average scattering beneath South and Central America, eastern Europe, and Indonesia.

Finally, it should be noted that the earliest onset time of observed PKP precursors agrees closely with that predicted for scattering at the CMB (e.g., Cleary and Haddon, 1972; Shearer et al., 1998). If scattering existed in the outer core at significant depths below the CMB, this would cause arrivals at earlier times than are seen in the data. This suggests that no observable scattering originates from the outer core, although a quantitative upper limit on small-scale outer-core heterogeneity based on this constraint has not yet been established. Such a limit would be useful to test the recent hypothesis of Dai and Song (2008) that movement of outer-core heterogeneities could explain their observations of increased temporal variability in travel times for core seismic phases compared to mantle phases.

1.24.3.7 PKKP Precursors and $PKKP_X$

PKKP is another seismic core phase that provides information on deep-Earth scattering. Precursors to PKKP have been observed within two different distance intervals. PKKP(DF) precursors at source–receiver distances beyond the B caustic near 125° are analogous to the PKP precursors discussed in the previous section and result from scattering in the mantle. Doornbos (1974) detected these precursors in NORSAR (Norwegian Seismic Array) records of Solomon Islands earthquakes and showed that their observed slownesses were consistent with scattering from the deep mantle. At ranges $<125°$, PKKP(BC) precursors can result from scattering off short-wavelength CMB topography. Chang and Cleary (1978, 1981) observed these precursors from Novaya Zemlya explosions recorded by the LASA array in Montana at about 60° range. These observations were suggestive of CMB topography but had such large amplitudes that they were difficult to fit with realistic models. Doornbos (1980) obtained additional PKKP(BC) precursor observations from NORSAR records from a small number of events at source–receiver distances between 80° and 110°. He modeled these observations with CMB topography of 100–200 m at 10–20 km horizontal scale length. Motivated by PKKP precursor observations (see the succeeding text), Cleary (1981) suggested that some observations of P′P′ precursors (e.g., Adams, 1968; Haddon et al., 1977; Husebye et al., 1977; Whitcomb and Anderson, 1970) might be explained as CMB-scattered PKKKP precursors.

A comprehensive study of PKKP(BC) precursors was performed by Earle and Shearer (1997), who stacked 1856 high-quality PKKP seismograms, obtained from the GSN at distances between 80° and 120°. PKKP is most readily observed at high frequencies (to avoid interference from low-frequency S coda), so the records were band-pass-filtered to between 0.7 and 2.5 Hz. To avoid biasing the stacked amplitudes, no consideration was given to the visibility or lack of visibility of PKKP precursors on individual records. The resulting stacked image showed that energy arrives up to 60 s before direct PKKP(BC) and that average precursor amplitudes gradually increase with time. Earle and Shearer (1997) modeled these observations using Kirchhoff theory for small-scale CMB topography. Their best-fitting model had a horizontal scale length of 8 km and RMS amplitude of 300 m. However, they identified a systematic misfit between the observations and their synthetics in the dependence of precursor amplitude with source–receiver distance. In particular, the Kirchhoff synthetics predict that precursor amplitude should grow with range but this trend is not apparent in the data stack. Thus, the model underpredicts the precursor amplitudes at short ranges and overpredicts the amplitudes at long ranges. Earle and Shearer (1997) and Shearer et al. (1998) explored possible reasons for this discrepancy between PKKP(BC) precursor observations and predictions for CMB topography models. They were not able to identify a very satisfactory explanation but speculated that scattering from near the ICB might be involved because it could produce precursor onsets that agreed with the observations (see Figure 13 from Shearer et al., 1998). However, scattering angles of 90° or more are required and it is not clear, given the expected amplitude of the direct PKKP(DF) phase, that the scattered amplitudes would be large enough to explain the PKKP(BC) precursor observations. They concluded that strong inner-core scattering would be required, which could only be properly modeled with a multiple-scattering theory. Regardless of the possible presence of scattering from

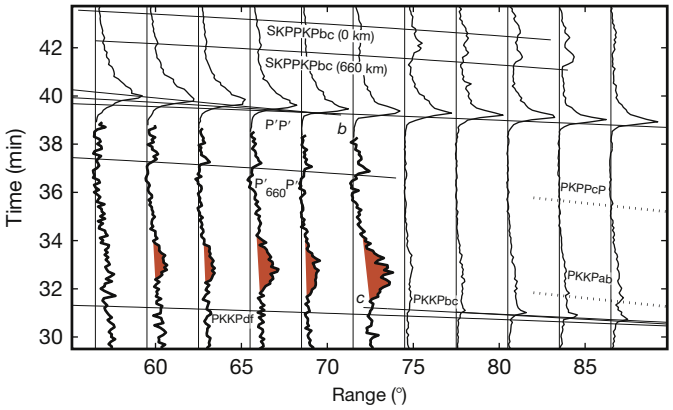

Figure 9 A stack of 994 seismograms from Earle and Shearer (1998), showing the $PKKP_X$ phase (red) in the high-frequency wavefield preceding P′P′. The stacked traces are normalized to the maximum P′P′ amplitude and are plotted with respect to the origin time of a zero depth earthquake. To better show the $PKKP_X$ arrival, amplitudes are magnified by eight for traces preceding P′P′ at epicentral distances $<73°$ (indicated by the heavy lines). Labels indicate observed phases and the position of the P′P′ b and PKKP c caustics.

sources outside the CMB, these PKKP(BC) precursor observations can place upper limits on the size of any CMB topography. Earle and Shearer (1997) concluded that the RMS topography could not exceed 315 m at 10 km wavelength.

Earle and Shearer (1998) stacked global seismograms using P′P′ as a reference phase and identified an emergent, long-duration, high-frequency wave train near PKKP (see **Figure 9**), which they named $PKKP_X$ because it lacked a clear explanation. $PKKP_X$ extends back from the PKKP(C) caustic at 72° to a distance of about 60°. Its 150 s long duration, apparent move-out, and proximity to PKKP suggest a deep scattering origin. However, Earle and Shearer were not able to match these observations with predictions of single-scattering theory for scattering in the lower mantle, CMB, or ICB. They speculated that some form of multiple-scattering model at the CMB might be able to explain the observations, perhaps involving a low-velocity zone just above the CMB to trap high-frequency energy, a model similar to that proposed to explain P_{diff} coda by Bataille et al. (1990), Tono and Yomogida (1996), and Bataille and Lund (1996). Earle (2002) further explored the origin of $PKKP_X$ and other scattered phases near PKKP by performing slant stacks on LASA data. His results suggested that, in addition to off-great-circle-path near-CMB scattering, near-surface P-to-PKP scattering is likely an important contributor to high-frequency energy around PKKP at distances between 50° and at least 116°. In particular, such scattering arrives at the same time as observations of PKKP precursors and $PKKP_X$, thus providing a possible explanation for why PKKP precursor amplitudes are hard to fit purely with CMB scattering models. However, quantitative modeling of P-to-PKP scattering has not yet been performed to test this hypothesis.

More recently, Rost and Earle (2010) examined PKKP precursors using small-aperture seismic arrays in Canada and India. Beamforming analysis showed regions of strong scattering near the CMB beneath the Caribbean, Patagonia, the Antarctic Peninsula, and southern Africa. The 1 Hz scattered energy suggests small-scale chemical heterogeneity, and Rost and Earle speculated that the scattering beneath Antarctica and the Americas is related to ancient subducted crust, whereas the southern Africa scattering may be related to partial melt associated with the edge of a large low shear velocity province just above the CMB in that region.

1.24.3.8 PKiKP and PKP Coda and Inner-Core Scattering

The ICB-reflected phase PKiKP is of relatively low amplitude and observations from single stations are fairly rare, particularly at source–receiver distances $<50°$. However, improved signal-to-noise ratio and more details can be obtained from analysis of short-period array data. Vidale and Earle (2000) examined 16 events at 58°–73° range recorded by the LASA in Montana between 1969 and 1975. As shown in **Figure 9**, a slowness versus time stack of the data (band-pass-filtered at 1 Hz) revealed a 200 s long wave train with an onset time and slowness in agreement with that predicted for PKiKP. They attributed this energy to scattering from the inner core because it arrived at a distinctly different slowness from late-arriving P coda and it was much more extended in time than LASA PcP records for the same events. The PKiKP wave train takes 50 s to reach its peak amplitude and averages only about 2% of the amplitude of PcP. Direct PKiKP is barely visible, with an amplitude close to its expected value, which is small because the ICB reflection coefficient has a node at distances near 72° (e.g., Shearer and Masters, 1990).

Vidale and Earle (2000) fitted their observations with synthetics computed using single-scattering theory applied to a model of random inner-core heterogeneity with 1.2% RMS variations in density and the Lamé parameters (λ and μ) and a correlation distance of 2 km, assuming an exponential autocorrelation model. They assumed ${}^{\alpha}Q_I = 360$ uniformly throughout the inner core, a value obtained from a study (Bhattacharyya et al., 1993) of pulse broadening of PKP(DF) compared to PKP(BC). They noted that without inner-core attenuation, the predicted scattered PKiKP wave train would take 100 s to attain its peak value and would last 350 s. The low value of ${}^{\alpha}Q_I$ resulted in only the shallow penetrating P waves retaining sufficient amplitude to be seen. Model-predicted scattering angles were near 90°, making the scattering most sensitive to variations in inner-core λ. Vidale and Earle (2000) found a trade-off between the various free parameters

in their model and picked their 2 km correlation length because it minimized the required RMS variation of 1.2% necessary to fit the observations. They computed a fractional energy loss of 10% from scattering in the top 300 km of the inner core, helping to justify the use of the Born single-scattering approximation. Vidale et al. (2000) examined LASA data for two nuclear explosions 3 years apart and separated by <1 km. They identified systematic time shifts in PKiKP coda, which they explained as resulting from differential inner-core rotation, as previously proposed by Song and Richards (1996). In contrast, much smaller time differences are observed in PKKP and PKPPKP arrivals, supporting the idea that the time dependence originates in the inner core. Vidale et al. (2000) estimated an inner-core rotation rate of 0.15° per year.

Cormier et al. (1998) measured pulse broadening in PKP(DF) waveforms and showed that they could be fitted either with intrinsic inner-core attenuation or with scattering caused by random layering (1D) with 8% P-velocity perturbations and 1.2 km scale length. Cormier and Li (2002) inverted 262 broadband PKP(DF) waveforms for a model of inner-core scattering attenuation based on the dynamic composite elastic medium theory of Kaelin and Johnson (1998) for a random distribution of spherical inclusions. They not only obtained a mean velocity perturbation of ~8% and a heterogeneity scale length of ~10 km but also observed path-dependent differences in these parameters, with both depth dependence and anisotropy in the size of the scattering attenuation. They suggested that scattering attenuation is the dominant mechanism of attenuation in the inner core in the 0.02–2 Hz frequency band. Cormier and Li (2002) argued that the large discrepancy in RMS velocity perturbation and scale length between their study (RMS = 8%, scale length = 10 km) and the model (RMS = 1.2%, scale length = 2 km) of Vidale and Earle (2002) may be due to the significant intrinsic attenuation assumed by Vidale and Earle and differences in depth sensitivity between the studies.

Poupinet and Kennett (2004) analyzed PKiKP recorded by Australian broadband stations and the Warramunga array for events at short distances ($<\sim45°$). They found that PKiKP could frequently be observed on single traces filtered at 1–5 Hz. In contrast to Vidale and Earle (2000), they found that PKiKP typically had an impulsive onset with a coda that decayed rapidly to a relatively small amplitude that persisted for more than 200 s. Although most of the Poupinet and Kennett results were for shorter source–receiver distances than the 58°–73° range of the Vidale and Earle study, they did analyze one event at 74° that exhibited similar behavior. Poupinet and Kennett suggested that the differences in the appearance of PKiKP coda between the studies may reflect different sampling latitudes at the ICB and different frequency filtering. They pointed to similarities in the appearance of PKiKP coda and P_{diff} coda (see the preceding text) and speculated that both result from their interaction with a major interface that may involve energy channeling to produce an extended wave train. Poupinet and Kennett (2004) argued that the high-frequency nature of PKiKP coda excludes an origin deep within the inner core where attenuation is high and suggested that multiple scattering near the ICB is a more likely mechanism.

Koper et al. (2004) analyzed PKiKP coda waves recorded by short-period seismic arrays of the International Monitoring System (IMS) at source–receiver distances ranging from 10° to 90°. Stacked beam envelopes for the 10°–50° data showed impulsive onsets for PcP, ScP, and PKiKP, but a markedly different coda for PKiKP, which maintained a nearly constant value that lasted for over 200 s. This is consistent with the Poupinet and Kennett (2004) results at similar distances and supports the idea that inner-core scattering is contributing to the PKiKP coda. At distances from 50° to 90°, Koper et al. (2004) found one event at 56° with a PKiKP coda that increased in amplitude with time, peaking nearly 50 s after the arrival of direct PKiKP, behavior very similar to the LASA observations of Vidale and Earle (2000). At 4 Hz, 13 out of 36 PKiKP observations had emergent codas that peaked at least 10 s into the wave train. However, more commonly, the peak coda amplitude occurred at the onset of PKiKP. Koper et al. (2004) found that the average PKiKP coda decay rate was roughly constant between stacks at short- and long-distance intervals, supporting the hypothesis of inner-core scattering. They argued that the best distance range to study inner-core scattering is 50°–75°, where the direct PKiKP amplitude is weak (because of a very small ICB reflection coefficient) so that scattering from the crust and mantle is unlikely to contribute as much to the observed coda as scattering from the inner core. However, they also discussed the possibility that CMB scattering could deflect a P wave into a PKiKP wave that could reflect from the ICB at an angle with a much higher reflection coefficient and contribute to the observed coda.

Leyton and Koper (2007a,b) applied single-scattering theory to model PKiKP coda observations and found that the emergent coda seen in previous observations (e.g., **Figure 10**) can only be produced by scattering in the uppermost 350 km of the inner core. They obtained an average Q_C of 500 for the inner core, but with a geographic dependence in which most PKiKP coda observations are from the Pacific Ocean and Asia and relatively few from the Atlantic. This implies that inner-core scattering has a hemispheric dependence, which has also been observed in other properties (e.g., anisotropy strength) of the outermost inner core. Peng et al. (2008) presented additional LASA records of PKiKP coda, which they forward modeled using the Monte Carlo seismic phonon code of Shearer and Earle (2004). Consistent with Leyton and Koper (2007a), they found that the general properties of the PKiKP coda could be explained with small-scale volumetric heterogeneities in the uppermost few hundred kilometers of the inner core. Cormier (2007) modeled both backscattered PKiKP and forward-scattering PKP(DF) waves at frequencies up to 1 Hz using a 2D pseudospectral finite-difference code and showed how an anisotropic texture with hemispheric variations could explain the observations. Cormier et al. (2011) further developed this model and related it to hypotheses for inner-core crystal growth. Calvet and Margerin (2008) proposed a model in which uppermost inner-core scattering and attenuation are explained with an aggregate of randomly oriented anisotropic blobs of aligned iron crystals.

$PKP(C)_{diff}$ is the P wave that diffracts around the ICB and is seen as an extension of the PKP(BC) branch to distances beyond 153°. Nakanishi (1990) analyzed Japanese records of $PKP(C)_{diff}$ coda from a deep earthquake in Argentina and suggested that scattering near the bottom of the upper mantle could explain its times and slowness. Tanaka (2005) examined $PKP(C)_{diff}$ coda from 28 deep earthquakes recorded using small-aperture short-period seismic arrays of the IMS at epicentral distances of 153°–160°. Beamforming at 1–4 Hz

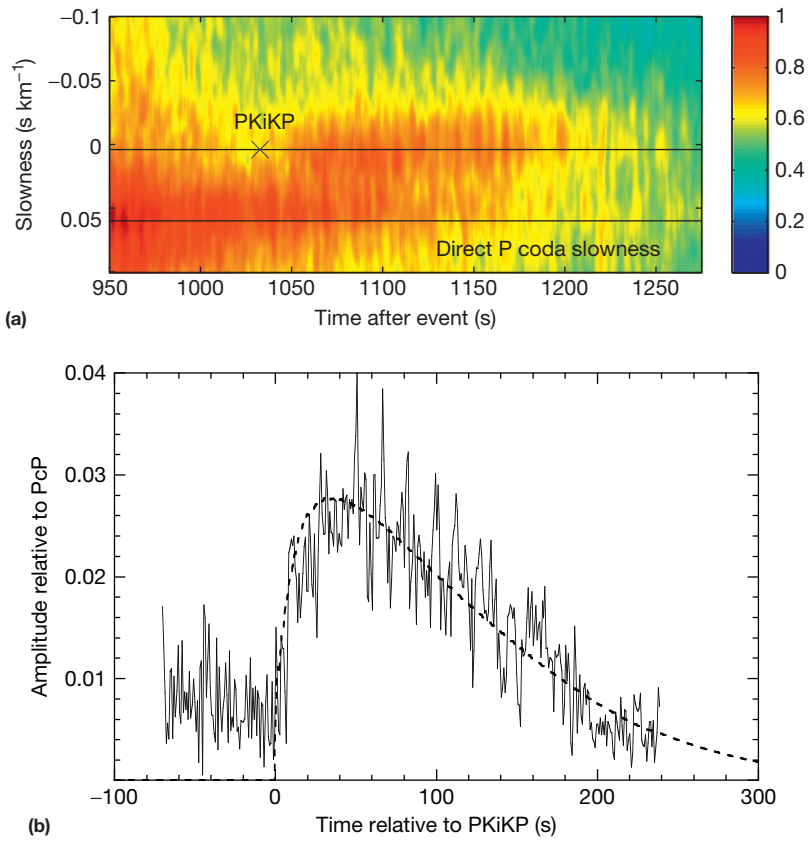

Figure 10 PKiKP coda as observed and modeled by Vidale and Earle (2000) for data from 12 earthquakes and four nuclear explosions recorded at the LASA in Montana. The top panel (Zhi-gang Peng, personal communication) shows a slowness versus time envelope function stack of energy arriving between 950 and 1270 s from the event origin times. The predicted direct PKiKP arrival is shown with the ×. Late P coda forms the stripe seen at a slowness near 0.5 s km^{-1}. PKiKP coda is the stripe seen near zero slowness. The bottom panel compares a PKiKP amplitude stack (wiggly line) to the predicted scattering envelope for an inner-core random heterogeneity model (dashed line).

resolved the slownesses and back azimuths of PKP(DF), PKP(C)$_{diff}$, and PKP(AB). The PKP(C)$_{diff}$ coda lasted longer than PKP(AB), but the wide slowness distribution of PKP(C)$_{diff}$ coda is difficult to explain as originating solely from the ICB, and Tanaka suggested that scattering near the CMB is an important contributor to PKP(C)$_{diff}$ coda.

Vidale and Earle (2005) studied PKP coda from seven Muruoa Island nuclear explosions over a 10-year period recorded by the NORSAR at an epicentral distance of 136°. They observed complicated arrivals lasting ∼10 s that were more extended than the relatively simple pulses observed for direct P waves from explosions recorded in the western United States. Vidale and Earle suggested that these complications likely arose from scattering at or near the ICB. They showed that small time shifts in the PKP coda were consistent with shifts predicted for point scatterers in an inner core that rotated at 0.05°–0.1° per year, although they could not entirely rule out systematic changes in source location.

1.24.3.9 Other Phases

Emery et al. (1999) computed the effect of different types of D'' heterogeneity on S_{diff}, using both the Langer and Born approximations. They found that their long-period S_{diff} observations are not particularly sensitive to the types of small-scale heterogeneities proposed to explain other data sets. Cormier (2000) used the coda power between P and PcP and S and ScS, together with limits on pulse broadening in PcP and ScS waveforms, to model D'' heterogeneity using a 2D pseudospectral calculation. He attempted to resolve the heterogeneity power spectrum over a wide range of scale lengths, to bridge the gaps among global tomography studies, D'' studies, and PKP precursor analyses.

Lee et al. (2003) noted an offset in S coda observations for Central Asian earthquakes (150–250 km deep) recorded about 750 km away at station AAK. The offset occurred near the ScS arrivals in coda envelopes at 10 and 15 s period. At shorter periods (1–4 s), a change in coda decay rate appeared associated with the ScS arrival. They simulated these observations with a Monte Carlo method based on radiative transfer theory and isotropic scattering. For a two-layer mantle model (separated at 670 km), their best-fitting synthetics at 4 s had a total scattering coefficient g_0 of about 1.3×10^{-3} km^{-1} and 6.0×10^{-4} km^{-1} for the upper and lower layers, respectively. Corresponding results at 10 s were about 4.7×10^{-4} km^{-1} and 2.6×10^{-4} km^{-1}. Lee et al. (2006) further studied S and ScS coda envelopes from deep earthquakes recorded at nine distributed global seismic stations and modeled the results with a Monte Carlo method with isotropic scattering and obtained estimates of both the frequency and depth dependence of

average mantle scattering. They also identified regions of stronger scattering, including beneath Central Asia and New Guinea, and argued that scattering attenuation is much stronger than intrinsic attenuation in the 4–10 s band for some regions.

1.24.4 Discussion

Scattering from small-scale irregularities has now been detected at all depths inside the Earth with the exception of the fluid outer core, although many details of this heterogeneity (power spectral density, depth dependence, etc.) remain poorly resolved, at least on a global scale. Scattering is the strongest near the surface, but significant scattering also occurs throughout the lower mantle (e.g., Cormier, 1999; Earle and Shearer, 2001; Hedlin et al., 1997; Margerin and Nolet, 2003b; Shearer and Earle, 2004; Shearer et al., 1998). Small-scale heterogeneity within the deep mantle is almost certainly compositional in origin because thermal anomalies would diffuse away over relatively short times (Hedlin et al., 1997; Helffrich and Wood, 2001) and supports models of incomplete mantle mixing (e.g., Allègre and Turcotte, 1986; Gurnis and Davies, 1986; Morgan and Morgan, 1999; Olson et al., 1984). Helffrich and Wood (2001) discussed the implications of small-scale mantle structure in terms of convective mixing models and suggested that the scatterers are most likely remnants of lithospheric slabs. Assuming subduction-induced heterogeneities are 11–16% of the volume of the mantle, they proposed that most of this heterogeneity occurs at scale lengths <4 km, where it would have little effect on typically observed seismic wavelengths. Meibom and Anderson (2003) discussed the implications of small-scale compositional heterogeneity in the upper mantle, where partial melting may also be an important factor.

There is a large gap between the smallest scale lengths resolved in global mantle tomography models and the ~10 km scale length of the random heterogeneity models proposed to explain scattering observations. Chevrot et al. (1998) showed that the amplitude of the heterogeneity in global and regional tomography models obeys a power law decay with wave number, that is, that most of the power is concentrated at low spherical harmonic degree, a result previously noted by Su and Dziewonski (1991) for global models. For the shallow mantle, this is probably caused in part by continent–ocean differences (G. Masters, personal communication, 2005), but a decay of order k^{-2}–k^{-3} is also predicted for heterogeneity caused by temperature variations in a convecting fluid (Cormier, 2000; Hill, 1978). However, this decay cannot be extrapolated to very small scales because it would predict heterogeneity much weaker than what is required to explain seismic scattering observations at ~10 km scale. As discussed by Cormier (2000), the most likely explanation is a change from thermal to compositionally dominated heterogeneity and that small-scale (<100 km) mantle perturbations are chemical in origin. Spherical heterogeneities of radii 38 km or smaller can be entrained in mantle flow, assuming a mantle viscosity of 10^{21} Pa s, a density contrast of 1 g cc^{-1}, and a convective velocity of 1 cm year^{-1} (Cormier, 2000). Because settling rate scales as the radius squared, smaller blobs will be entrained even at much smaller density contrasts.

The role of the core–mantle and ICBs in small-scale scattering is not yet clear. The D'' region has stronger heterogeneity than the midmantle in tomography models, and large velocity contrasts have been identified in specific regions, including ULVZs and strong individual PKP scatterers (e.g., Niu and Wen, 2001; Vidale and Hedlin, 1998; Wen and Helmberger, 1998). However, globally averaged PKP precursor studies do not find evidence for stronger scattering at the CMB than in the rest of the lower mantle (Hedlin et al., 1997; Margerin and Nolet, 2003b). CMB topography can also produce scattering and has been invoked by some authors to explain PKP and PKKP precursors but fails to predict globally averaged PKKP precursor amplitude versus distance behavior (Earle and Shearer, 1997). Vidale and Earle modeled PKiKP coda observations with bulk scattering within the inner core, while Poupinet and Kennett (2004) suggested that scattering from near the ICB, where several recent studies have found evidence for anomalous structures (e.g., Koper and Dombrovskaya, 2005; Krasnoshchekov et al., 2005), was more likely responsible for their PKiKP coda observations. Strong attenuation is observed in the inner core, but it is not yet clear how much of this is caused by intrinsic versus scattering attenuation. Inner-core scattering might be caused by small-scale textural anisotropy (Cormier et al., 1998, 2011; Vidale and Earle, 2000) or by compositionally induced variations in partial melt (Vidale and Earle, 2000).

At shallow depths, it is clear that there are both strong scattering and significant lateral variations in scattering strength, but the number and diversity of studies on lithospheric scattering make it difficult to draw general conclusions. There is a large literature on both the theory of seismic scattering and on coda observations, but there has been much less effort to integrate these studies into a comprehensive picture of scattering throughout Earth's interior. Review articles (e.g., Aki, 1982; Fehler and Sato, 2003; Herraiz and Espinoa, 1987; Matsumoto, 1995; Sato, 1991) and the book by Sato and Fehler (1998, 2012) are certainly helpful, but their summaries often involve comparisons among studies that differ in many key respects, such as their choice of seismic phase (P, S, etc.); their epicentral distance, frequency range, and time window; and their modeling assumptions (e.g., single scattering, MLTW, finite difference, and radiative transfer). It is not always clear whether models proposed to explain one type of data are supported or contradicted by other types of data. For example, models with horizontally elongated crust and/or upper-mantle heterogeneity appear necessary to explain long-range P_n propagation across Eurasia, and many models of lower crustal reflectors are anisotropic (e.g., Holliger and Levander, 1992; Wenzel et al., 1987). Tkalčić et al. (2010) proposed anisotropic scattering from near-receiver random heterogeneity to explain their observations of anticorrelated PcP and PKiKP amplitudes. Yet almost all modeling of local earthquake coda assumes isotropic random heterogeneity.

A promising development is the increasingly open availability at data centers of seismic records from local and regional networks, portable experiments, and the GSNs. This should enable future coda studies to be more comprehensive and analyze larger numbers of stations around the world using a standardized approach. This would help to establish a baseline of globally averaged scattering properties and maps of

lateral variations in scattering strength over large regions. Data from small-aperture seismic arrays are also very important, because they permit beamforming analysis that can pinpoint the locations of individual scatterers or scattering regions, as several recent studies have shown (e.g., Cao and Romanowicz, 2007; Miller and Niu, 2008; Rost and Earle, 2010; Rost et al., 2008; Thomas et al., 2009). Ultimately, more detailed information on lithospheric heterogeneity (amplitude, scale length, and anisotropy) will enable more detailed comparisons to geologic and petrologic constraints on rock chemistry (e.g., Levander et al., 1994; Ritter and Rothert, 2000).

Analyses of deep-Earth scattering have also used a variety of different phase types and modeling approaches. Even today, there are still fundamental features in the high-frequency wavefield, such as $PKKP_X$ (Earle, 2002), that lack definitive explanations and have never been quantitatively modeled. However, given recent improvements in modeling capabilities (e.g., Monte Carlo calculations based on radiative transfer theory and whole Earth finite-difference calculations), there is now a clear path toward creating 1D models of Earth's average scattering properties and resolving between scattering and intrinsic attenuation mechanisms. It appears that a substantial part of seismic attenuation at high frequencies is caused by scattering rather than intrinsic energy loss, but fully resolving trade-offs between Q_{Sc} and Q_I will require analysis of scattering observations at a wide range of frequencies and epicentral distances. An interesting comparison can be made with seismologist's efforts to map bulk seismic velocity variations. Regional velocity profiling of the upper mantle gave way in the 1980s to comprehensive velocity inversions (i.e., 'tomography') to image global 3D mantle structure. This required working with large data sets of body-wave travel-time and surface-wave phase-velocity measurements and developing and evaluating methods to invert large matrices. The earliest models were crude and controversial in their details, but rapid progress was made as different groups began comparing their results. We may be poised to make similar advances in resolving Earth scattering. But progress will require improved sharing of data from local and regional networks as well as greater testing and standardization of numerical simulation codes. As models of small-scale random heterogeneity become more precise, comparisons to geochemical and convection models will become increasingly relevant.

1.25.1 Introduction

Seismic waves have long been known to attenuate at a rate greater than that predicted by geometric spreading of their wave fronts. Knopoff (1964) pointed out more than four decades ago that much of that attenuation must occur because of the intrinsic anelastic properties of the Earth. Were it not for that fortunate circumstance, waves generated by all past earthquakes, as noted by Knopoff, would still be reverberating in the Earth today. Since it redistributes rather than absorbs wave energy, scattering would not have the same effect.

A commonly used measure of the efficiency of wave propagation is the quality factor Q or its inverse, the internal friction Q^{-1}. The latter quantity is most often defined by the expression

$$Q^{-1} = \Delta E / 2\pi E_{\max} \quad [1]$$

where ΔE is the elastic energy lost per cycle and $E_{\max}$ is the maximum elastic energy contained in a cycle. O'Connell and Budiansky (1978) proposed replacing maximum energy by average stored energy in eqn [1], a change that requires the integer 4 replace 2 in that equation. That form of the definition permits writing Q as the ratio of the real to imaginary part of the complex elastic modulus. However, most seismologists use eqn [1].

Because of its strong dependence on temperature, partial melting, and water content, mapping anelastic attenuation in the Earth has the potential to provide valuable information on Earth's three-dimensional (3D) structure and dynamics, in complement to what can be learned from mapping elastic velocities. A significant challenge is to separate the effects of anelastic (or intrinsic) attenuation from those of elastic scattering and focusing due to propagation in elastic 3D structure.

Practical aspects of seismic-wave attenuation include the need to account for it when determining earthquake magnitudes and when computing realistic synthetic seismograms. In addition, seismologists must know the attenuation structure in the Earth if they wish to determine dispersion that is produced by anelasticity (Jeffreys, 1967; Liu et al., 1976), which is needed, in particular, to interpret seismic models in the light of other observables such as the geoid (e.g., Romanowicz, 1990). The principle of causality requires that such velocity dispersion accompany intrinsic attenuation (Futterman, 1962; Lomnitz, 1957; Strick, 1967).

The following sections present a review of our current knowledge about seismic-wave attenuation from earliest studies to the present. It is a rapidly growing field for which measurements have only recently become sufficiently numerous and reliable to allow mapping at relatively small scales. It has consistently been observed that measurement errors are large, and it has recently become clear that systematic, rather than random, errors are the greatest cause of concern in Q determinations.

A major consideration is the frequency dependence of Q. After a brief review of earliest studies, we thus begin by describing the state of understanding of this issue. Next, we discuss 1D models of Q: Even now, only the average variation of Q with depth is reasonably constrained in the deep Earth, and frequency-dependent differences between the upper and lower mantle are emerging from the analysis of high-quality global data accumulated over the last 20 years. Following that, we discuss regional variations of Q in the upper mantle and in the crust, for which robust constraints are beginning to emerge. Earlier reviews on this topic can be found in Mitchell (1995) for the crust, Romanowicz (1998) for the mantle, and, most recently, Romanowicz and Durek (2000) for the whole Earth. This review is an updated version of Romanowicz and Mitchell (2007).

1.25.2 Early Studies

Although seismic-wave attenuation did not become a popular area of research until the 1970s, the first contributions appeared not long after global deployments of seismographs in the early 1900s. Here, we describe several important studies completed before 1970, which, in addition to providing the first estimates of Q for several phases, provided the first inklings of the difficulties associated with amplitude measurements.

Angenheister, working in Göttingen, Germany, in 1906, reported the first known measurements of the attenuation rate of a seismic wave. Instruments at that time were still primitive and surface waves consequently dominated most seismograms recorded by Göttingen's Wiechert seismometers. Angenheister (1906) used records from those instruments to measure the amplitude decay of 20 s surface waves for three different segments of the same great-circle path and found the decay rate to be about 0.00025 km^{-1}. For group velocities near 3 km s^{-1}, that rate corresponds to a Q value of about 200, a value implying that the measured attenuation coefficient lies within the range of commonly measured 20 s values today. He later published what was probably the first report of regional variations of surface-wave attenuation (Angenheister, 1921) in which he found that the decay of surface-wave amplitudes along oceanic paths was greater than that along continental paths. This result holds only for those cases where attenuation over relatively low-Q oceanic paths is compared to attenuation over high-Q continental paths (Mitchell, 1995).

Gutenberg also made some early determinations of Q using surface waves. He determined a Q value of 70 for Love waves at 100 s period (Gutenberg, 1924) and a value of 200 for Rayleigh waves at 20 s period (Gutenberg, 1945b). The latter value corresponds well with Angenheister's earlier measurement of Rayleigh-wave attenuation at that period. Gutenberg also determined Q for body phases, first finding a Q of 1300 for 4 s P and PKP waves (Gutenberg, 1945a). He then measured Q for three body-wave phases at different periods (Gutenberg, 1958), finding Qs of 2500 for P and PP at 2 s and 400 for P and PP at 12 s. In the same study, he also measured Q for S waves, finding values of 700 at 12 s and 400 at 24 s. Press (1956) also determined Q for S waves, finding it to be 500 or less.

Evernden (1955) studied the arrival directions of SV-, Rayleigh-, and Love-wave phases using a tripartite array in California and found that all of those phases deviated from great-circle paths between the events and the array. Although Evernden did not address Q, he brought attention to the fact that seismic waves may deviate from a great-circle path during propagation, a problem that continues, to this day, to plague determinations of Q from amplitude measurements.

The 1960s produced the first definitive evidence for lateral variations of body-wave Q even over relatively small distances. Asada and Takano (1963), in a study of the predominant periods of teleseismic phases recorded in Japan, found that those periods differed at two closely spaced stations and attributed that to differences in crustal Q. Ichikawa and Basham (1965) and Utsu (1967) studied spectral amplitudes at 0.5–3.0 Hz frequencies and concluded that P-wave absorption beneath a seismic station at Resolute, Canada, was greater than that beneath other stations in northern Canada.

Tryggvason (1965) devised a least-squares method for simultaneously obtaining Rayleigh-wave attenuation coefficients and source amplitudes using several stations located at varying distances from an explosive source. Since he assumed the source radiation pattern in this method to be circular, he had no need to determine that pattern or know the crustal velocity structure. In the same year, Anderson et al. (1965)

developed equations that allowed measured surface-wave attenuation to be inverted for models of Q_μ variation with depth and applied it to long-period surface waves that were sensitive to anelasticity at upper mantle depths.

Sutton et al. (1967) studied radiation patterns for Pg and Lg phases recorded at several stations in the United States and found that focusing and regional attenuation differences affected both waves. They concluded that the nature of the tectonic provinces traversed by the waves was more important than initial conditions at the source in determining the observed radiation patterns.

1.25.3 Frequency Dependence of *Q*

Determinations available in the 1960s from seismic observations and laboratory measurements suggested that Q was only weakly dependent on frequency (Knopoff, 1964). That conclusion, however, conflicted with the frequency dependence known for single relaxation mechanisms that exhibit rather narrowly peaked spectra for Q^{-1} centered at a characteristic frequency. Liu et al. (1976) reconciled those two observations by considering that, over the seismic frequency band in the Earth, Q^{-1} consists of a superposition of many thermally activated relaxation mechanisms for which maxima occurred at different frequencies. That superposition produces a continuous absorption band with a nearly frequency-independent Q^{-1} distribution in the seismic frequency band (**Figure 1**). The high- and low-frequency limits of the absorption band are described by relaxation times τ_1 and τ_2 and result in the following expression for the absorption band model (Kanamori and Anderson, 1977):

$$Q^{-1}(\omega) = (2/\pi)Q_m^{-1}\tan^{-1}\left[\omega(\tau_1 - \tau_2)/\left(1 + \omega^2\tau_1\tau_2\right)\right] \qquad [2]$$

where Q_m represents the maximum within the absorption band. A more realistic distribution of relaxation times yields a mild frequency dependence $Q \approx \omega^\alpha$ within the absorption band (Minster and Anderson, 1981; Mueller, 1986), with $Q^{-1} \sim \omega^{+1}$ at the higher end of the absorption band and $Q^{-1} \sim \omega^{-1}$ at the low end (Minster and Anderson, 1981). Measurements of attenuation of multiple ScS phases (Sipkin and Jordan, 1979) and other body waves (e.g., Der et al., 1982; Lundquist and Cormier, 1980; Sacks, 1980; Ulug and Berckhemer, 1984) have provided evidence that the high-frequency corner is located in the band 0.1–1 Hz. A later model (Anderson and Given, 1982) constructed to explain variations of Q for various depths in the Earth from the comparison of surface wave, free oscillation, and body-wave data obtained a single absorption band with $Q_\mu = 80$, $\alpha = 0.15$, and a width of five decades centered at different frequencies for different depths in the mantle, with a shift of the absorption band to longer periods at greater depth. Such a model could satisfy many of the known values of Q in the early 1980s. In particular, $\alpha = 0.15$ is compatible with a study of the damping of the Chandler wobble (Smith and Dahlen, 1981).

Many years of body-wave studies have since constrained the frequency dependence $Q \propto \omega^\alpha$ in the body-wave band to have $\alpha \sim 0.1$–1. Ulug and Berckhemer (1984) used spectral ratios of S/P waves in the frequency range 0.04–1.5 Hz and found

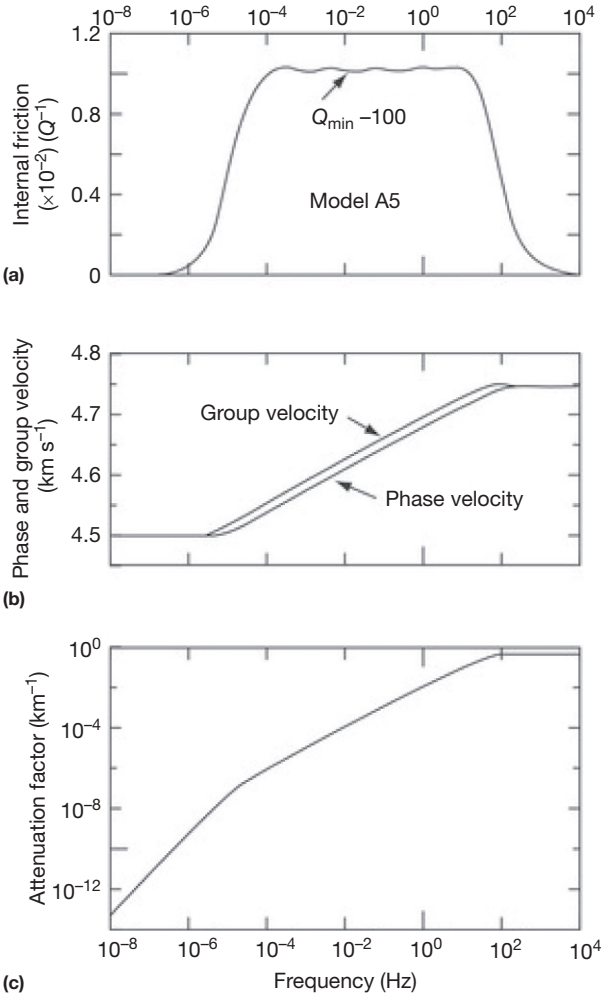

Figure 1 (a) Internal friction (Q^{-1}), (b) phase and group velocity dispersion, and (c) attenuation coefficient as functions of frequency. Reproduced from Liu HP, Anderson DL, and Kanamori H (1976) Velocity dispersion due to anelasticity: Implication for seismology and mantle composition. *Geophysical Journal of the Royal Astronomical Society* 47: 41–58, with permission from Blackwell Publishing.

$\alpha \sim 0.25$–0.6. This frequency range was extended to 6 Hz by Cheng and Kennett (2002), who found $\alpha \sim 0.2$–1 in Australia. Flanagan and Wiens (1998) found a factor of 2 difference in Q measured from sS/S and pP/P phase pairs in the Lau back-arc region, implying a strong frequency dependence in the 1–10 s period range, and inferred $\alpha \sim 0.1$–0.3.

More recently, Shito et al. (2004) used regional waveform data in western Pacific subduction zones to estimate α from P–P spectral ratios in the frequency range 0.08–8 Hz and found a range of $\alpha \sim 0.1$–0.4, which is in agreement with laboratory studies for solid olivine (e.g., Gueguen et al., 1989; Jackson, 2000) and seems to indicate that solid-state processes are the primary mechanism for the observed attenuation. Indeed, according to laboratory results, partial melting results in weak frequency dependence in a broad frequency range (e.g., Jackson et al., 2004), which is inconsistent with these observations.

In order to reconcile teleseismic S–P differential travel times measured by handpicking, on the one hand, and by

comparison of observed and synthetic seismograms, on the other, Oki et al. (2000) found that a frequency dependence with $\alpha \sim 0.04$ needs to be introduced in the reference preliminary reference Earth model (PREM) Q model (Dziewonski and Anderson, 1981), a value much smaller than in other studies.

More recently, Lekic et al. (2009) applied a Backus–Gilbert approach to globally averaged normal mode and surface-wave measurements in order to isolate the frequency dependence from that due to the frequency dependence reflecting the depth sensitivity of Q_μ. They found that α varies with frequency within the period range considered (80–3000 s), with $\alpha \sim 0.3$ at periods shorter than 200 s (compatible with most body-wave results), decreasing to ~0.1 between 300 and 800 s and possibly becoming negative at even longer periods (**Figure 2**). From most recent comparisons of global 1D Q models obtained from surface waves and free oscillations, on the one hand, and teleseismic P and S body waves, on the other, it appears that this frequency dependence is manifested primarily in the lower mantle (see **Section 1.25.4**).

At crustal depths, the frequency dependence of Q is usually described by the equation $Q = Q_0 f^{\zeta}$ where Q_0 is a reference frequency and ζ is the frequency dependence parameter. For shear-wave Q (Q_μ), it appears to be between about 0.0 and 1.0 and varies regionally, with depth in the crust and with frequency, as will be described in more detail in a later section.

An important consequence of the frequency dependence of Q in the Earth is the presence of velocity dispersion due to attenuation. Velocity dispersion was first recognized to be important when comparing global mantle elastic velocity models based on free oscillation and body-wave travel time data centered at 1 s. A dispersion correction of 0.5–1.5% helped reconcile these models (Kanamori and Anderson, 1977; Liu et al., 1976) and has been applied systematically in global seismology (e.g., Dziewonski and Anderson, 1981), although Montagner and Kennett (1996) showed that attenuation alone is insufficient to reconcile both types of data and suggested the need to perturb the density structure and introduce radial anisotropy in different parts of the mantle. In the presence of large lateral variations in Q in the upper mantle, which could be in excess of 100%, it is also necessary to account for velocity dispersion when interpreting global tomographic models in the light of other geophysical data, such as the geoid, as illustrated by Romanowicz (1990) in the case of very long wavelength structure. Karato (1993) estimated the contribution of anelasticity to the calculation of partial derivatives of elastic velocities with temperature and concluded that it should be important in the deep mantle, as anelastic effects might dominate anharmonic effects at high pressures, a conclusion confirmed by Karato and Karki (2001), who used an improved model for the calculation of anelastic effects, including the nonlinear dependence of attenuation on temperature.

In order to interpret seismologically derived 1D and 3D Q models in the Earth, it is necessary to confront them with laboratory experiments, which should provide constraints on (1) the physical mechanisms responsible for attenuation (i.e., grain boundary or dislocation processes (e.g., Jackson, 1993; Karato, 1998)) and the related frequency dependence and (2) the dependence of Q on temperature and pressure. Unfortunately, this has proven to be a major challenge, particularly for the deep mantle, due to the difficulties of reproducing in the laboratory both the high P and high T conditions, the low frequency range of seismic observations, and the location of the absorption band far from the frequency range of ultrasonic experiments, preventing ready extrapolation of seismic frequencies.

The variation of Q_μ with temperature can be expressed as (e.g., Jackson, 1993; Karato, 1993)

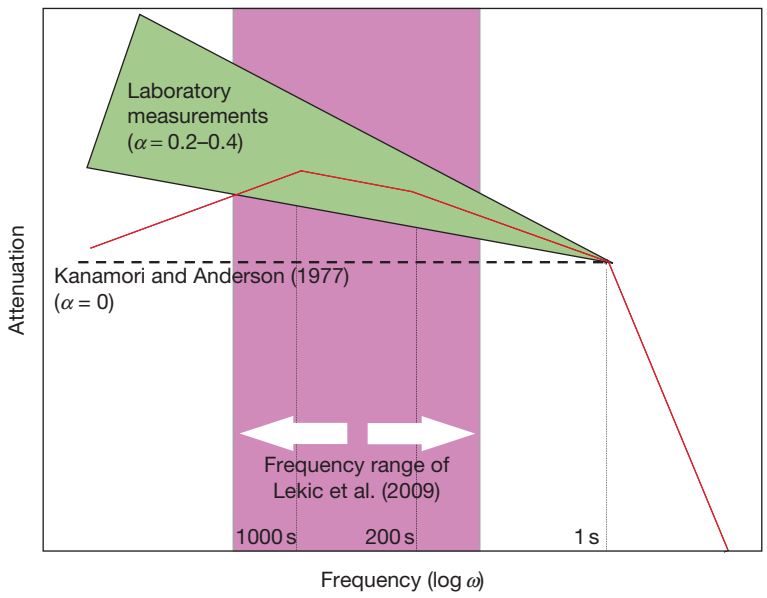

Figure 2 Frequency dependence of attenuation within the absorption band obtained from low-frequency data. A corner frequency is assumed at 1 Hz, beyond which $\alpha = 1$ (Sipkin and Jordan, 1979). Seismically inferred values (pink) are compared to those obtained from laboratory measurements (green) and the estimates assuming no frequency dependence (broken line). After Lekic V, Matas J, Panning M, and Romanowicz B (2009) Measurement and implications of frequency dependence of attenuation. *Earth and Planetary Science Letters* 282: 285–293.

$$Q^{-1} = A\omega^{-\alpha}\exp(-\alpha H/RT) \quad [3]$$

where $H = E^* + PV^*$ is the activation enthalpy, which depends on pressure through the activation volume V^*, a quantity that is not precisely known. One way to circumvent this is to parametrize this expression in terms of homologous temperature T_m/T (e.g., Cammarano et al., 2003; Karato, 1993; Sato et al., 1989):

$$Q^{-1} = A\omega^{-\alpha}\exp(-\alpha g T_m/T) \quad [4]$$

where g is a dimensionless factor, which depends on H, the melting temperature T_m, and the gas constant R. Such a parametrization removes the need for accurate knowledge of the activation volume and also allows the use of a simple scaling law to relate grain size to frequency (Sato et al., 1989). The pressure dependence is folded into T_m, which is easier to measure in the laboratory.

Much progress in the measurement of attenuation at seismically relevant frequencies has been achieved in the last 15 years (e.g., Faul et al., 2004; Getting et al., 1997; Jackson, 1993; Jackson and Faul, 2010; Karato and Spetzler, 1990). Recently, reliable results for olivine have become available at pressures and temperatures down to asthenospheric depths. There is some evidence that attenuation scales with diffusion creep viscosity (e.g., McCarthy and Takei, 2011), that hydration of mantle minerals causes significant increases in attenuation (Aizawa et al., 2008), and that water (Shito et al., 2006) and melt (Faul et al., 2004; McCarthy et al., 2011) can significantly increase attenuation. Research continues into the mechanism of attenuation, including grain boundary sliding (Morris and Jackson, 2009), diffusion creep (Sundberg and Cooper, 2010), and the effect of dislocations (Farla et al., 2012). These recent advances are described in more detail in **Chapter 2.21**.

While most physical mechanisms invoked consider volumetric contributions to attenuation in the Earth (e.g., Jackson, 2007), several authors have pointed out recently that solid–solid phase transitions may play a role in bulk dissipation of seismic energy, through the finite character of their kinetics. However, this process is clearly strongly frequency-dependent, and there is no agreement yet on the relevance of the attenuation band to seismically relevant frequencies (e.g., Durand et al., 2012; Li, 2010; Ricard et al., 2009). Nevertheless, global 1D mantle Q profiles are generally readily interpreted in terms of thermally activated, viscoelastic relaxation mechanisms (e.g., Faul and Jackson, 2005; see also **Chapter 2.21**).

1.25.4 1D Global Mantle *Q* Models

Our knowledge of the 1D Q structure of the Earth comes from two types of data spanning different ranges of frequencies: normal modes/surface waves, on the one hand, and body waves, on the other. Because of the suggestive evidence for frequency dependence of Q, with an upper frequency limit for the corresponding absorption band falling in the range of body-wave studies, it is important to consider these two types of models separately before comparing them. Another issue is that of lateral variations in Q and how representative the sampling might be in different types of studies: for example, normal mode data, by the nature of their global sampling, will likely provide models that are more representative of the true global average than multiple ScS data, which sample primarily subduction zone regions and their vicinities. A third issue is that some bulk attenuation appears to be needed to explain normal mode data, but different authors locate it in different parts of the mantle.

1.25.4.1 Normal Mode and Surface-Wave-Based 1D *Q* Mantle Models

As noted in a previous review of this topic (Romanowicz and Durek, 2000), early studies based on normal mode and surface-wave data developed measurement and inversion methodologies and established the main features of the variation of Q_μ with depth (e.g., Anderson and Archambeau, 1966; Buland and Gilbert, 1978; Deschamps, 1977; Geller and Stein, 1978; Gilbert and Dziewonski, 1975; Jobert and Roult, 1976; Kanamori, 1970; Roult, 1975; Sailor and Dziewonski, 1978). These studies found that

1. shear-wave attenuation is low in the lithosphere;
2. there is a high-attenuation zone roughly corresponding to the low-velocity zone generally associated with the asthenosphere;
3. below 200 km depth, Q_μ increases with depth with a sharp gradient across the transition zone; and
4. Q_μ is higher on average in the lower mantle than in the upper mantle.

In the last decades, an intriguing discrepancy has emerged between the measurements of fundamental mode Q_R obtained for spheroidal modes using a propagating wave approach (e.g., Durek and Ekström, 1996; Durek et al., 1993; Dziewonski and Steim, 1982; Romanowicz, 1990, 1994a) and those using a standing-wave approach (Roult and Clévédé, 2000; Smith and Masters, 1989; Widmer et al., 1991). In the period band 150–300 s, where measurements by the two methods overlap, Q_R estimates derived from standing-wave observations are systematically higher than those derived from surface waves by about 15–20%, which translates into higher Q_μ in the transition zone for models based on free oscillation data (**Figure 3**). The cause of this discrepancy was first investigated by Durek and Ekström (1997) who explored the influence of realistic background noise on normal mode-based measurements, which require the use of long time series. This issue is particularly relevant in the light of the discovery of continuously excited background free oscillations (e.g., Suda et al., 1998). While the background noise does contribute to a bias toward higher Q values, if measurements are done with care, the bias does not exceed about 5–10%, failing to explain the larger observed discrepancy. On the other hand, Masters and Laske (1997) questioned the accuracy of surface-wave Q measurements at very long periods, pointing out the difficulty in finding an appropriate time window isolating the fundamental mode in the presence of overlapping wave trains and overtones. A more recent study by Roult and Clévédé (2000) confirms the higher Q values obtained from mode-based measurements (**Figure 3**). These authors concluded that mode Q measurements are more reliable than measurements

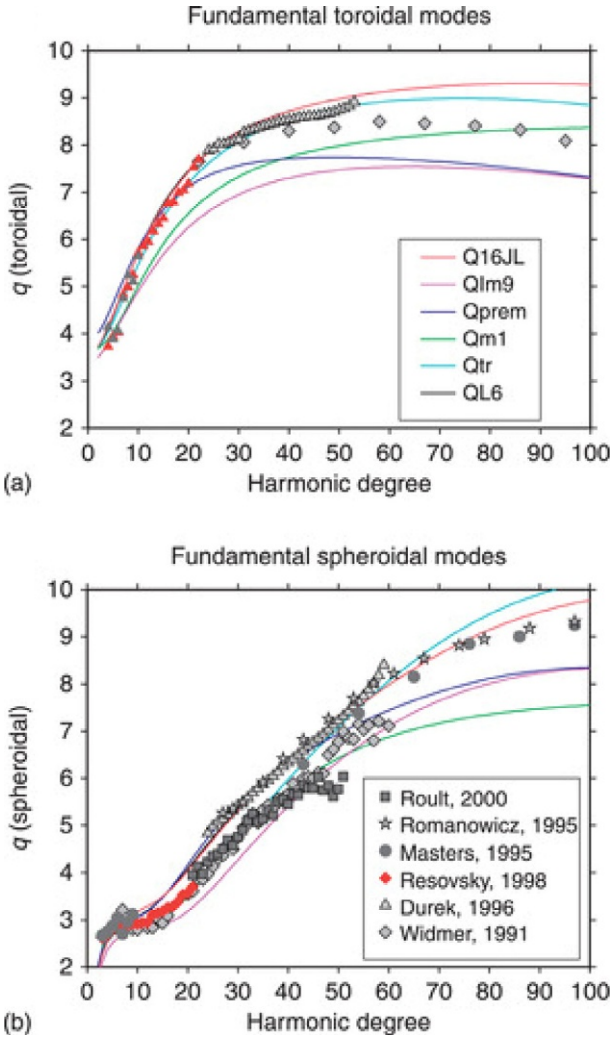

Figure 3 Fundamental-mode Q measurements obtained using either a standing mode approach (Masters and Laske, 1997; Roult and Clévédé, 2000; Widmer et al., 1991) or a propagating surface-wave approach (Durek and Ekström, 1996; Romanowicz, 1995). Note the discrepancy between the two approaches in the frequency band where both methods can be applied. Also shown are fits to the data for several models of Q_μ shown in Figure 3. (a) Toroidal modes and (b) spheroidal modes. Data are from the REM website.

based on great-circle surface-wave amplitude ratios, which they attribute to contamination by higher modes and to the relative deficiency in low frequencies of the first arriving R1 train. We note however that the QL6 model of Durek and Ekström (1996) was derived from traveling surface-wave data using a different method than tested by Roult and Clévédé (2000). QL6 (**Figures 3** and **4**) not only fits surface-wave data better than mode-based models such as QM1 (Widmer et al., 1991) but also fits toroidal mode Q data better than both QM1 and PREM (Dziewonski and Anderson, 1981). Therefore, it seems that the question of the mode/surface-wave discrepancy has not been resolved yet. A more recent study by Resovsky et al. (2005) revisited the construction of a 1D Q model of the Earth using a forward modeling approach based on the neighborhood algorithm and produced a family of acceptable models with robust error estimates. Their mode data set was augmented through recent measurements of the attenuation of low-angular-order modes (e.g., He and Tromp, 1996; Resovsky and Ritzwoller, 1998). They circumvented the mode/surface-wave discrepancy problem by including both fundamental-mode surface-wave and spheroidal mode measurements in the period range 150–300 s and attributing a low weight to these incompatible data. Their final family of models appears to be in good agreement, on average, with the surface-wave-based model QL6, in particular in the transition zone (**Figure 4**). While PREM and QL6 have constant Q_μ in the lower mantle, the Resovsky et al. (2005) study tentatively includes three layers in the lower mantle and confirms the presence of a mild Q_μ maximum in the mid-lower mantle (Qtr, **Figure 3**), as was found in earlier models (SL8, Anderson and Hart (1978); PAR2C, Okal and Jo (2002); QM1, Widmer et al. (1991); and Q7U15L, Durek and Ekström (1996); see the review by Romanowicz and Durek (2000)). What is perhaps not yet well constrained is the precise location of this maximum.

1.25.4.2 Body-Wave-Based 1D Mantle *Q* Models

Body-wave studies typically derive Q structure from the measurement of t^* ('t-star'), which is defined as follows:

$$t^* = \int \frac{ds}{Qv} \qquad [5]$$

where the integral is taken along the body-wave path and v is the wave velocity. See **Section 1.25.6.2** for more details on how t^* is measured.

Nearly vertically traveling multiple ScS waves provided early constraints on the average Q_μ in the whole mantle (e.g., Kovach and Anderson, 1964; Yoshida and Tsujiura, 1975) and confirmed the increase in Q_μ in the mid-mantle. Studies of amplitude ratios of body-wave phases interacting with the core–mantle boundary (CMB) provided early evidence for a possible lower Q_μ zone at the base of the mantle (e.g., Kuster, 1972; Mitchell and Helmberger, 1973).

More recently, Lawrence and Wysession (2006a) developed a Q_μ model based on a large global data set of differential ScS/S amplitude measurements, using a niching genetic algorithm to fit the variations of these amplitudes with distance. Because of the nature of their data, their model (QLM9, **Figure 4**) is best constrained in the lower mantle, so they chose to fix the top 400 km of the mantle to the PREM value. The resulting model also provides evidence for the existence of a Q_μ maximum in the lower mantle, in this case right above the D″ region. However, the high Q values that they obtain in the transition zone are incompatible with the fundamental-mode spheroidal and toroidal data (**Figure 3(a)**). Replacing their upper mantle with that of QL6 solves this problem (**Figure 3(b)**), and little adjustment is needed in the lower mantle to fit the ScS/S amplitude data (Lawrence, personal communication).

Most recently, Durand et al. (2013) applied a method based on instantaneous frequency measurements (Ford et al., 2012; Gao et al., 2011) to obtain differential t^*_{S-ScS} estimates in the northeast Pacific and under Central America with a strict data quality selection. These authors infer a 1D Q_μ profile of the mantle that is generally in good agreement with QLM9

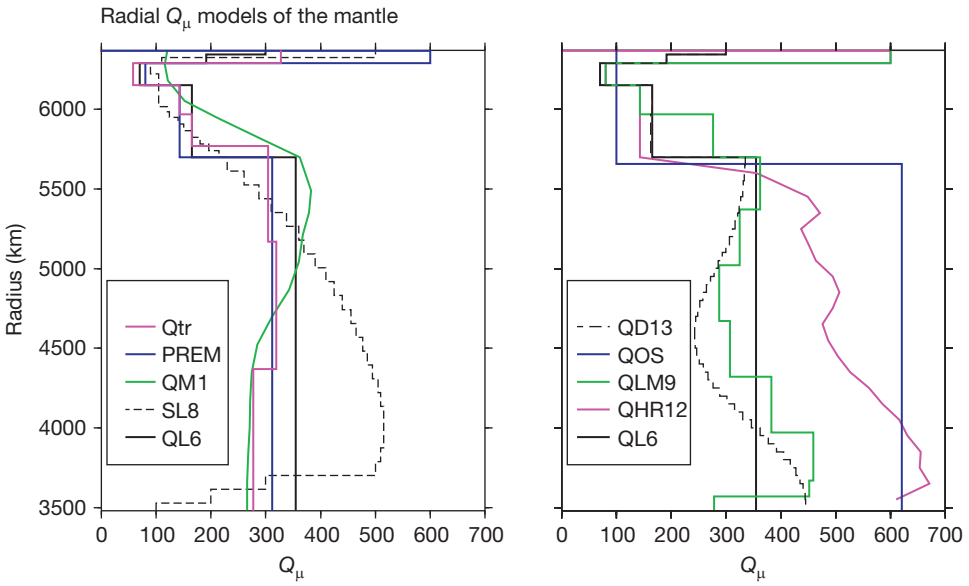

Figure 4 Radial models of Q_μ in the mantle. (Left panel) Free oscillation and surface-wave-based models. Models QM1 (Widmer et al., 1991); SL8 (Anderson and Hart, 1978); PREM (Dziewonski and Anderson, 1981); QL6 (Durek and Ekström, 1996); and Qtr (Resovsky et al., 2005). PREM and QL6 fit fundamental-mode Rayleigh-wave data, but only QL6 also fits fundamental-mode toroidal mode data. (Right panel) Body-wave-based models: QLM9 (Lawrence and Wysession, 2006a) from ScS/S amplitude data; QI6JL: a model that fits both ScS/S amplitude data and fundamental-mode surface-wave data (Lawrence, personal communication); QOS08 (Oki and Shearer, 2008); QHR12 (Hwang and Ritsema, 2011). The latter two models are based on teleseismic P and S waves.

(Figure 4). They suggest that differences can be attributed to a slight frequency dependence with $\alpha \sim 0.1$.

The typical frequency range of studies based on ScS and multiple ScS is about 0.02–0.2 Hz. Higher frequency studies have been based on a combination of P and S waves or P and PP waves. Warren and Shearer (2000) derived a series of 1D global Q_α models from stacked spectra of P and PP waves in the frequency band 0.16–0.86 Hz. While frequency dependence cannot be ignored in this frequency band, as discussed further in the following text, when assuming no frequency dependence, these authors find that the upper mantle is five times more attenuating than the lower mantle.

Recently, Oki and Shearer (2008) constructed a two-layered 1D Q_μ model for short-period body waves (3–10 s), using a large data set of measurements from teleseismic P and S waves from broadband seismograms and extracting differential t^*_{S-P} measurements. They obtained similar average Q_μ in the upper mantle as derived from long-period surface-wave/mode measurements but higher Q_μ (by a factor of 2) in the lower mantle, which they inferred to indicate stronger frequency dependence of Q_μ in the lower mantle. Hwang and Ritsema (2011) reexamined this question with an order of magnitude larger data set and confirmed the larger Q_μ in the lower mantle. Their proposed model (model HR11, Figure 4), which has a fixed upper mantle Q_μ profile equal to that of PREM (Dziewonski and Anderson, 1981), features increasing Q_μ from 360 at the top of the lower mantle to 670 in the lowermost mantle. The authors point out that this difference with depth is as large as lateral differences in Q_μ between tectonic and stable areas of the continents. The details of the lower mantle structure may change if the upper mantle model QL6 (Durek and Ekström, 1996) is used rather than PREM, as would be appropriate to fit long-period surface waves. However, the general trend of Q_μ increasing with depth in the lower mantle, which is the most robust feature of model HR11, would not change.

Clearly, the large differences between the Q values obtained from body waves, especially those including P waves in the analysis, and low-frequency surface waves and free oscillations suggest a frequency-dependent effect. Moreover, this effect may be different in the upper and lower mantle. To accommodate both normal mode and body-wave observations, Anderson and Hart (1976, 1978) proposed a model with a Q_μ maximum in the lower mantle, a feature that has successively appeared and disappeared in subsequent whole mantle models based on normal mode and surface-wave data (Giardini and Woodhouse, 1988; Li, 1990; Masters and Gilbert, 1983; Okal and Jo, 2002; Smith and Masters, 1989; Widmer et al., 1991). Anderson and Given (1982) proposed that the absorption band is shifted to lower frequencies in the lower mantle, compared to the upper mantle, resulting in a more prominent frequency dependence in the lower mantle. This is in agreement with the results of Oki and Shearer (2008). On average, the large differences between lower mantle Q values derived from low-frequency and high-frequency data can be accommodated with a frequency dependence with $\alpha \sim 0.1$, as also noted by Lekic et al. (2009) (Figure 2).

In these body-wave studies, it is generally assumed that bulk attenuation (Q_κ^{-1}) can be neglected. Using the relationship between Q_α, Q_β, and Q_κ (Anderson and Hart, 1978)

$$Q_\alpha^{-1} = \frac{4}{3}(V_S/V_P)^2 Q_\beta^{-1} + \left[1 - \frac{4}{3}(V_S/V_P)^2\right] Q_\kappa^{-1} \qquad [6]$$

this leads to the commonly used conversion between Q_α and Q_β, assuming a Poisson solid ($V_S = \sqrt{3}V_P$):

$$Q_\alpha = \frac{9}{4} Q_\beta$$

However, some regional studies in subduction zones suggest that bulk attenuation could be as large as 1/3 of attenuation in shear (e.g., Roth et al., 1999).

Bulk attenuation is necessary to simultaneously fit high-Q radial mode data and surface-wave data, and some models such as SL8 (Anderson and Hart, 1978) and the widely used PREM (Dziewonski and Anderson, 1981) locate it in the inner core, while others prefer to place it in the upper mantle (e.g., Sailor and Dziewonski, 1978), in the outer core (Anderson and Given, 1982; Widmer et al., 1991), and, more recently, in the asthenosphere (Durek and Ekström, 1995). Resovsky et al. (2005) also revisited this question and found bulk attenuation to be negligible in the inner core and preferentially located in the outer core and lower mantle. The issue of the location of bulk attenuation in the Earth is not resolved.

New constraints on average shear and bulk attenuation in the Earth and the core and their frequency dependence, from a combination of body-wave and normal mode analysis, may be forthcoming, owing to the high-quality digital data set assembled in the last 20 years on the global broadband seismic network and owing to the occurrence of several very large earthquakes, especially great earthquakes such as that in Sumatra on 26 December 2004 and Tohoku (Japan) on 12 March 2010. In particular, these data are providing an opportunity to revisit the Qs of the gravest modes of the Earth, in particular the radial mode ${}_0S_0$, and, for the first time, measure the Q of individual singlets of modes such as ${}_0S_2$ or ${}_2S_1$ (e.g., Rosat et al., 2005; Roult et al., 2006).

1.25.5 *Q* in the Core

1.25.5.1 The Outer Core

In the liquid outer core, Q is very high, and generally well approximated by $Q_\kappa \sim \infty$, to fit both free oscillation and body-wave data. Finite Q_κ is, however, required to explain some free oscillation data in the outer core, but the depth range where it is located is still the subject of debate (Anderson and Given, 1982; Durek and Ekström, 1996; Resovsky et al., 2005; Widmer et al., 1991) and, in general, the upper mantle and the inner core are preferred locations for finite Q_κ. Likewise, while some evidence for finite Q_κ from short-period core phases has been suggested, it is not clear that it is resolvable (Cormier and Richards, 1976). There is some indication for the existence of a thin layer of relatively low Q just above the inner core boundary (ICB) (Zou et al., 2008), which could be due to the presence of suspended solid particles in the F-layer (Jeffreys, 1939; Loper and Roberts, 1981).

1.25.5.2 Attenuation in the Inner Core

Attenuation in the inner core is investigated using inner core-sensitive modes, as well as spectral amplitude ratios of different core phases. Topics that have been the subject of recent work include

- the compatibility of normal mode and body-wave measurements and implications for the frequency dependence of Q in the inner core,
- variations with depth,
- anisotropy in Q_α, and
- hemispheric variations at the top of the inner core.

From early on, measurements of amplitude ratios of PKP(DF) (sampling the inner core) and PKP(BC) (sampling the outer core) constrained Q_α in the top 500 km of the inner core to be in the range 200–600 (e.g., Bhattacharyya et al., 1993; Bolt, 1977; Choy and Cormier, 1983; Cormier, 1981; Doornbos, 1974, 1983; Ivan et al., 2005; Niazi and Johnson, 1992; Sacks, 1969; Song and Helmberger, 1993; Tseng et al., 2001). Most studies have suggested an increase of Q_α with depth, although some find that Q_α is constant with depth (e.g., Bhattacharyya et al., 1993; Niazi and Johnson, 1992). In these studies, the sampling depth range was limited by the narrow distance range in which the phase PKP(BC) is observed. Extending the depth range sampled by previous studies to 600 km by including diffracted PKP(BC) phases, Souriau and Roudil (1995) proposed a two-layered model with $Q_\alpha \sim 200$ in the topmost 100 km of the inner core and $Q_\alpha \sim 440$ below. Cormier et al. (1998) designed a new approach that allowed them to investigate the variation of Q_α deeper in the inner core, by comparing observed and synthetic PKIKP waveforms in the distance range 150–180°. The synthetic waveforms are built using the source time history of each earthquake, determined from the analysis of P waveforms, and include the effects of mantle attenuation. In a recent improved implementation of this method, which takes into account surface reflections and reverberations near the source, Li and Cormier (2002) obtained a mean for the inner core of Q_α 307 ± 90 and much stronger attenuation in the top 300 km of the inner core. Testing the hypothesis of an innermost inner core, Cormier and Stroujkova (2005) found a rapid change in the magnitude and variance of seismic attenuation of PKIKP in the middle of the inner core, in the interval 400–600 km in Earth radius (**Figure 4**), which supports the existence of a distinct innermost inner core (e.g., Ishii and Dziewonski, 2002). Recently, Waszek and Deuss (2013) have suggested the presence of a high-Q_α layer in the top 30 km of the inner core.

While the analysis of core-sensitive PKP phases provides constraints on Q_α, normal modes primarily provide constraints on Q_μ. If there were no significant attenuation in bulk, and no frequency dependence, the inferred Q_μ from body-wave studies would be on the order of ~40. Confronting this value with measurements based on inner core-sensitive normal mode data has resulted in some puzzles. Early normal mode studies found very large values of Q_μ (1500–3500) based on the measurement of attenuation of spheroidal core modes (Buland and Gilbert, 1978; Masters and Gilbert, 1981), whereas most more recent models have much lower Q_μ, such as PREM ($Q_\mu = 85$; Dziewonski and Anderson, 1981) or QM1 ($Q_\mu = 110$; Widmer et al., 1991), which is also compatible with measurements of Giardini and Woodhouse (1988). On the other hand, applying the Sompi method, Kumazawa et al. (1990) and Suda and Fukao (1990) measured Q_μ of modes sensitive to shear in the top part of the inner core and found very large values and an increase with depth, with $Q_\mu = 1500$ in the top 200 km and $Q_\mu = 3800$ at greater depth. However, their identification of modes has been questioned, and, recently, Andrews et al. (2006) have shown that measurements of

inner core Q_μ could be biased by neglecting mode coupling. Through the comparison of observations and synthetic predictions including mode coupling effects, these authors found that models with very high Q_μ are incompatible with the observations, which favor moderate values of $Q_\mu \sim 80–100$. While such moderate values are now established in the top part of the inner core, where normal modes concentrate their sensitivity, a recent observation of PKJKP, which samples deep into the inner core (Cao et al., 2005), has provided the opportunity to estimate the average Q_μ in the inner core, which was found to be >150, possibly as large as 300 (Cao and Romanowicz, 2009), and which would imply an increase with depth, like that for Q_α. This result, however, needs to be confirmed by additional observations of PKJKP.

Even the lowest proposed values for Q_μ currently favored are incompatible with the Q_α results, unless one invokes either (1) significant bulk attenuation in the inner core, or (2) significant frequency dependence of Q, or (3) a significant scattering component. The rather low value for Q_α found is compatible with the existence of a mushy zone in the top part of the inner core, whose presence is related to the process of solidification of iron alloy (Fearn et al., 1981; Loper and Fearn, 1983; Loper and Roberts, 1981) involving a solid matrix and fluid inclusions. This would result primarily in compressional attenuation and could explain some of the observations of seismic anisotropy in the inner core (e.g., Singh et al., 2000). Bowers (2000) cautioned that the large scatter observed in Q_α measurements from PKP amplitude ratios could be due to the effects of lateral variations in structure near the CMB and in particular the presence of ultralow-velocity zones. On the other hand, Krasnoshchekov et al. (2005) suggested that variability in the amplitudes of ICB reflected PKiKP phases could be due to a mosaic of partially molten patches of scale length 10–100 km.

In a series of papers, Cormier and collaborators recently explored two different interpretations for the attenuation in the inner core, invoking a viscoelastic mechanism and a scattering mechanism, respectively (Cormier and Li, 2002; Cormier et al., 1998; Li and Cormier, 2002). In the viscoelastic interpretation, they considered the absorption band model of Cormier and Richards (1988) and, through a parameter search approach, sought to constrain the low-frequency corner τ_1, as well as the peak attenuation Q_m^{-1} and the attenuation at 1 Hz (Li and Cormier, 2002). While constraining τ_1 turned out to be problematic, they found that the data are consistent with frequency-dependent attenuation in the inner core and weak velocity dispersion in the seismic body-wave band. The existence of scattering, at least at the top of the inner core, was clearly documented by Vidale and Earle (2000) through the modeling of PKiKP coda and more recently by Leyton and Koper (2007). In the scattering interpretation, Cormier and Li (2002) investigated a model of inner core attenuation due to forward scattering by 3D fabric caused by solidification texturing, which could also be responsible for the observed depth-dependent inner core anisotropy. They found a mean scale length of heterogeneity of 9.8 ± 2.4 km and a mean velocity perturbation of $8.4 \pm 1.8\%$. They confirmed the depth dependence found in the viscoelastic interpretation but with a sharper transition between the highly attenuating upper part of the inner core and the lower attenuating center (e.g., Figure 13 in Souriau and Calvet, 2015). They suggested that scattering plays a dominant role in attenuating inner core traversing phases in the frequency band 0.02–2 Hz, as it can also explain elastic and anelastic anisotropy and their depth dependence and helps reconcile the body-wave and normal mode Q measurements. A synthesis of waveform and travel time observations led Cormier (2007) to propose a model of texture of the uppermost inner core that may reflect the solidification process of the inner core.

1.25.5.2.1 Hemispheric variations

Another observation in favor of the presence of a mushy transition zone at the top of the inner core is that of hemispheric differences, first observed in elastic velocity using differential travel time measurements of the pair of phases PKP(BC), PKP(DF) (Creager, 1999; Tanaka and Hamaguchi, 1997). A pair of useful phases for the study of hemispheric variations in attenuation is (PKiKP, PKIKP) in the distance range 120–144°. In this distance range, PKiKP is postcritically reflected at the ICB and PKIKP samples the top ~100 km of the inner core (Garcia, 2002; Niu and Wen, 2001). These phases have almost the same ray paths in the mantle and in the outer core, so the differences in travel times and amplitudes can be attributed to the vicinity of the ICB. Indeed, in a study covering the epicentral distance range 131–141°, the faster eastern hemisphere (40–180 °E) was also found to have lower Q_α than the slower western hemisphere (Wen and Niu, 2002). In order to better constrain the depth dependence of the hemispheric variations in Q_α, Cao and Romanowicz (2004) extended the epicentral distance range to 144° and found large differences in Q_α, with $Q_\alpha \sim 335$ in the western hemisphere and ~160 in the eastern hemisphere, which they interpreted as resulting from small lateral temperature variations at the top of the inner core. Such temperature variations could be imposed on the inner core by heterogeneities at the CMB (e.g., Sumita and Olson, 1999) and would influence the connectivity of fluid inclusions in the mushy zone. Below about 85 km depth, the hemispheric differences appeared to wane. However, several studies found evidence for persisting differences at greater depth. Oreshin and Vinnik (2004) measured spectral ratios of PKP(DF) and either PKP(AB) or PKP(BC) in the distance range 150–170° and found differences in Q_α between the hemispheres down to 600 km depth. Yu and Wen (2006a) combined observations of PKiKP/PKIKP in the distance range 120–141° and PKP(BC)/PKIKP in the distance range 146–160°, along equatorial paths, and proposed that they could resolve hemispheric differences in Q down to at least 200 km (**Figure 5**). However, in the distance range 149–155°, PKP(BC) interferes with PKiKP, causing large scatter in the data. On the other hand, Li and Cormier (2002) did not find evidence for such hemispheric variations in the deeper inner core using PKIKP data at larger distances.

Recently, depth-dependent attenuation structure was constrained in the inner core below the north East Pacific (western hemisphere), using PKP data from the dense short-period HiNet array in Japan (Iritani et al., 2010; Kazama et al., 2008). These authors found evidence for a peak in attenuation around 200–250 km depth, which may provide constraints on the mode of growth of the inner core. Most recently, lopsided growth of the inner core has been proposed to explain seismic

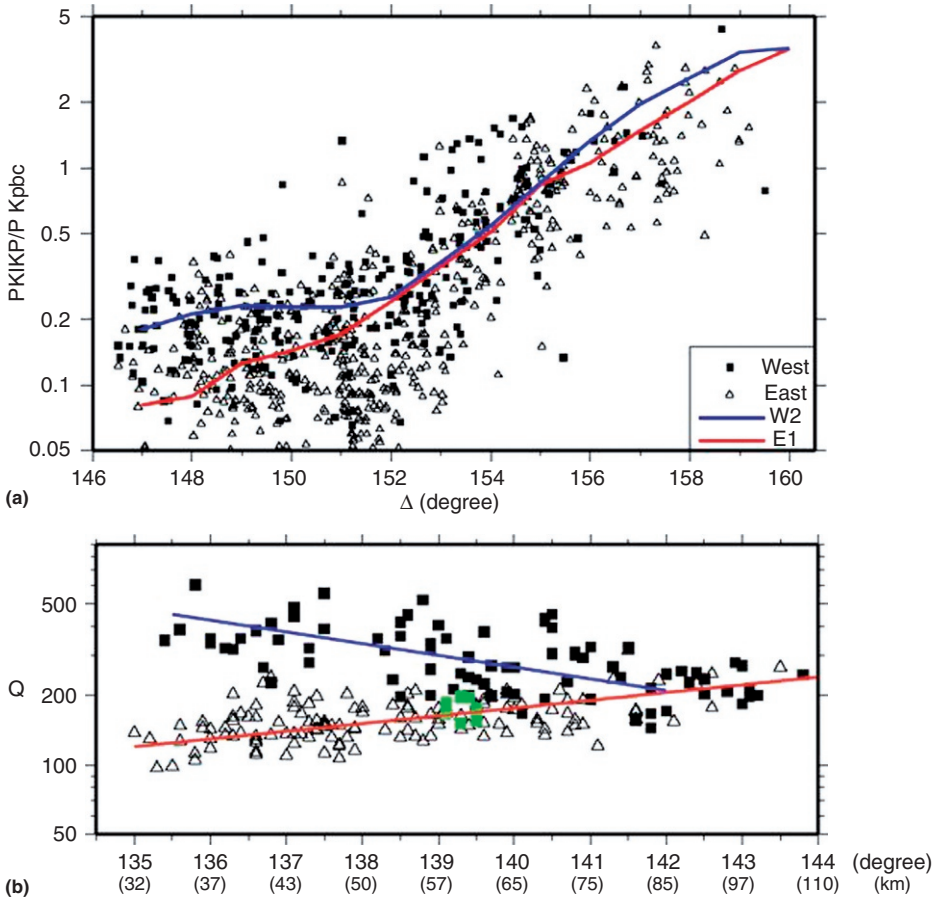

Figure 5 Hemispheric variations of *Q* in the inner core. hemispheric variations in the inner core (Alboussière et al., 2010; Monnereau et al., 2010).

1.25.5.2.2 Anisotropic attenuation

The presence of velocity anisotropy is well documented for the inner core (e.g., Creager, 1992; Morelli et al., 1986; Shearer, 1994; Su and Dziewonski, 1990; Vinnik et al., 1994; Woodhouse and Wong, 1986). Theoretical studies indicate that anisotropy in attenuation should accompany anisotropy in velocity, and several authors have noted the stronger attenuation of PKP(DF) phases traveling along polar paths (Creager, 1992; Song and Helmberger, 1993). Anisotropy in attenuation was first proposed by Souriau and Romanowicz (1996), who examined a carefully selected data set of PKP(DF)/PKP(BC) amplitude ratios for paths whose turning points were located under western Africa and for which good azimuthal coverage was available. They found a significant correlation between high attenuation and high velocity and inferred that the origin of anisotropy in the top half of the inner core must be due to the orientation of iron crystals, which would produce this type of correlation (Carcione and Cavallini, 1995), rather than fluid inclusions, which would result in correlation of high velocity with low attenuation (Peacock and Hudson, 1990). These results were subsequently extended to a global data set (Souriau and Romanowicz, 1997) and to antipodal paths (Cormier et al., 1998). Using an effective medium theory, Singh et al. (2000) proposed that both velocity and attenuation anisotropy could be explained by a model of oblate fluid inclusions aligned in the equatorial plane. Li and Cormier (2002) suggested that anisotropy in attenuation also varies with depth and preferred a scattering interpretation. Oreshin and Vinnik (2004) confirmed the correlation of anisotropy in attenuation with that in velocity, which, however, may not be present at high latitudes (Helffrich et al., 2002). Yu and Wen (2006b) confirmed these global trends from measurements of amplitude ratios of PKIKP/PKiKP and PKIKP/PKPbc, finding an average Q_α for polar paths of 200–250, in contrast to 600 for equatorial paths in the top 200 km of the inner core. More recently, the need for attenuation anisotropy in the inner core was challenged by Waszek and Deuss (2013), who analyzed an extended data set of PKIKP/PKiKP amplitude ratios, confirming the hemispheric variations in Q_α. These

authors noted that most previous studies did not take into account hemispheric variations in velocity when interpreting amplitude ratios of core-sensitive phases and suggested that these velocity variations alone could account for apparent attenuation anisotropy.

For more details on inner core attenuation, see **Chapter 1.23**.

1.25.6 Global 3D Attenuation Structure in the Upper Mantle

1.25.6.1 Normal Modes and Long-Period Surface Waves

1.25.6.1.1 Early studies

In the 1970s, after the occurrence of the 1960 Great Chilean Earthquake (Mw 9.6), and with the accumulation of data from the World-Wide Standardized Seismographic Network, measurements of long-period surface-wave attenuation, then based on relatively few records, showed large disagreements (e.g., Ben-Menahem, 1965; Jobert and Roult, 1976; Mills and Hales, 1978; Smith, 1972). At that time, it was realized that (1) elastic effects were important in limiting the accuracy of Q measurements; (2) anelastic attenuation caused frequency dependence of elastic velocities, which needed to be taken into account (Akopyan et al., 1976; Kanamori and Anderson, 1977; Liu et al., 1976; Luh, 1974; Randall, 1976); and (3) large systematic lateral variations existed, correlated with those of phase velocities and suggesting significant differences in attenuation under different tectonic regions, with low attenuation under shields and high attenuation under oceans and tectonically active provinces (e.g., Dziewonski and Steim, 1982; Lee and Solomon, 1979; Nakanishi, 1978, 1979b, 1981; Roult, 1982).

Most global upper mantle 3D Q models up to now, as we will discuss in the succeeding text, have been on surface waveform or amplitude data. However, several authors attempted to measure lateral variations in Q from normal mode data, which in principle should provide sensitivity at greater depths in the mantle. Because the mode amplitude data set is very contaminated by elastic effects (e.g., Smith and Masters, 1989), it was possible to recover only the longest wavelengths in the even-degree structure (Romanowicz et al., 1987; Roult et al., 1984; Suda et al., 1991). The most important result of these early studies is the presence of a long wavelength, degree 2, structure in Q_μ in the transition zone, shifted toward the west with respect to the degree 2 in the shallower mantle, with lowest Q centered in the central Pacific Ocean and under Africa.

1.25.6.1.2 Anelasticity and focusing

One of the main issues limiting resolution in global mantle attenuation tomography is the contamination of amplitudes by elastic focusing effects. Numerous cases of such contamination in Earth circling mantle waves have been reported. For example, for moderate size earthquakes, for which the effect of source directivity can be ruled out, one expects successive Rayleigh-wave trains to gradually decrease in amplitude, due to the effects of attenuation and geometric spreading. However, it is sometimes observed that an R_{n+1} train has larger amplitude than R_n, where n is the orbit number of the Rayleigh wave (e.g., Lay and Kanamori, 1985; Romanowicz, 1987, 2002), and such observations can be qualitatively reproduced by including focusing effects in synthetic seismograms obtained by normal mode summation (e.g., Romanowicz, 1987). Also in the frequency domain, long-period surface-wave amplitude spectra are often irregular, with many 'holes' that cannot be attributed to intrinsic attenuation or source effects (e.g., Romanowicz, 1994a).

To first order, in the framework of single scattering and in the high-frequency approximation, analytic expressions have been obtained for the focusing effect, both in a propagating wave formalism (Woodhouse and Wong, 1986) and in a normal mode asymptotic formalism (Park, 1987; Romanowicz, 1987). Using asymptotic approximations in the framework of normal mode theory, it was shown that focusing effects depend on the transverse gradients of elastic structure, as expressed in terms of phase velocity perturbations, in the case of propagating waves, and of local frequency perturbations, in the case of normal modes. The expressions obtained in both approaches are equivalent (Romanowicz, 1987). In the propagating surface-wave case and in the frequency domain,

$$\ln \delta A_F(\omega) = \frac{1}{2}\operatorname{cosec}\Delta \int_0^\Delta \left[\sin(\Delta-\phi)\sin\phi\,\partial_\theta^2 - \cos(\Delta-2\phi)\partial_\phi\right]\frac{\delta c}{c_0}(\omega)\,\mathrm{d}\phi \qquad [7]$$

where Δ is epicentral distance, ϕ is the angular distance along the source-station great-circle path, $\delta c/c_0$ is the relative perturbation in phase velocity along the path, and $\delta A_F(\omega)$ is the contribution to the amplitude at frequency ω due to focusing.

In the standing-wave case and time domain, for an isotropic source,

$$\delta F_k(\Delta) = \frac{a\Delta}{U}\left(\frac{\hat{D}_k - \widetilde{D}_k}{2k} + \frac{\cot\Delta}{8k}\left(\delta\hat{\omega}_k - \delta\widetilde{\omega}_k\right)\right) \qquad [8]$$

where $F_k = (1+\delta F_k(\Delta))$ is the perturbation to the time domain amplitude of the seismogram for multiplet k and $\delta\hat{\omega}_k$ and $\delta\widetilde{\omega}_k$ are the perturbations to the great-circle average and minor are average local frequencies for that multiplet respectively, $k = l + 1/2$, where l is the angular order of the mode, and we have defined

$$\widetilde{D} = \frac{1}{\Delta}\int_0^\Delta \partial_\Gamma(\delta\omega_k(s))\,\mathrm{d}s$$
$$\hat{D} = \frac{1}{2\pi}\int_0^{2\pi} \partial_\Gamma(\delta\omega_k(s))\,\mathrm{d}s \qquad [9]$$

where ∂_Γ denotes the second transverse derivative along the great-circle path, which reduces to the integrand in eqn [7]. Accounting for the radiation pattern in eqn [8] is equivalent to using eqn [7] together with ray tracing.

Because the focusing effects are so strongly dependent on the transverse gradients of the elastic structure, and because those are not generally well constrained, compounded by the fact that these expressions are approximate and valid only to first order, it has been a difficult challenge, for the last decade, to properly account for focusing effects in surface-wave attenuation tomography. Indeed, if the corrections made on the basis of an existing elastic model are inaccurate, they can potentially introduce more biases than they can correct.

Noting that focusing effects and attenuation behave very differently as Rayleigh waves circle around the Earth, with the

sign of attenuation always the same, while focusing/defocusing depends on the direction of propagation along the great circle, Romanowicz (1990) and Durek et al. (1993) showed that, by using four consecutive Rayleigh-wave trains, one can eliminate, at least to first order, the effect of focusing, as well as uncertainties in the source amplitude. This resulted in the first, low-degree, even-degree global tomographic models of attenuation in the upper mantle, which confirmed the existence of a strong degree 2 in attenuation, as first suggested in studies based on normal modes. These models showed that attenuation in the uppermost mantle was correlated with seismic velocities, at least at the longest wavelengths (~4000 km). There are two drawbacks to this approach: First, only even-degree structure can be retrieved in this fashion, as only great-circle average attenuation can be measured, and second, elastic effects become increasingly more pronounced as distance increases, and the first-order approximation is not suitable for higher orbit trains, leading to a decrease in the ability to retrieve the intrinsic attenuation signal. Moreover, higher orbit trains are more dispersed, limiting the frequency range in which consecutive Rayleigh-wave trains do not interfere with each other and/or with overtones.

In order to be able to retrieve odd-degree structure while not explicitly correcting for unknown focusing effects, and avoiding the drawbacks of using multiple orbit wave trains, a different approach was proposed by Romanowicz (1995), using three consecutive Rayleigh-wave trains (R1, R2, and R3). She noted that the R1 and R2 trains are the least contaminated by focusing effects. However, their amplitudes also depend on uncertainties in the source amplitude. The source amplitude shift varies slowly with frequency and can be estimated by comparing the overall level of the amplitude spectrum computed in two different fashions: (1) directly from R1 (or R2) and (2) using a linear combination of R1, R2, and R3 (Romanowicz, 1994a). This approach, combined with a rigorous data selection in which all R1 and R2 amplitude spectra that were not smoothly varying with frequency were rejected, led to the first low-degree (equivalent to about degree 5) tomographic model of upper mantle shear attenuation, QR19 (Romanowicz, 1995). Even though this first model had very low resolution, it confirmed the correlation of lateral variations of Q with V_S in the top 250 km of the upper mantle and a shift to a different pattern in the transition zone, dominated by low Q in the central Pacific and Africa and correlated with hotspots. Romanowicz (1994b) showed that, in the transition zone, at least at the longest wavelengths, anelastic attenuation correlated with the hotspot distribution, whereas the velocity structure correlates better with the slab distribution, consistent with expectations that Q is more sensitive to high temperature regions. The desensitizing approach used, however, limited the lateral resolution of the model obtained, since a relatively small number of paths qualified for inclusion in the inversion.

The applicability of the linear asymptotic approximation to the computation of focusing (eqns [7]–[9]) has been tested by Selby and Woodhouse (2000) on a large data set of Rayleigh-wave amplitudes on minor and major arcs, in the period range 73–171 s. These authors derived maps of lateral variations of $q_R(\omega) = Q_R^{-1}(\omega)$ at different frequencies, assuming that the amplitude of a fundamental-mode Rayleigh wave observed at distance Δ and angular frequency ω can be written as

$$A(\omega, \Delta) = A_0(\omega)(1 + F(\omega))\exp[-\omega a \Delta \widetilde{q}_R(\omega)]/2U_0(\omega) \quad [10]$$

where U_0 is group velocity, a is the radius of the earth, $A_0(\omega)$ is source term, and $\widetilde{q}_R(\omega)$ is the average Rayleigh-wave attenuation along the source-station path:

$$\widetilde{q}_R(\omega) = \frac{1}{\Delta}\int_0^{\Delta} q_R(\omega, s)\mathrm{d}s \quad [11]$$

$F(\omega)$ represents the effect of focusing, which can be calculated from a reference elastic 3D model using expression [6]. Selby and Woodhouse (2000) compared the maps obtained by (1) inverting the observed amplitude data set for lateral variations in Q_R without correcting for focusing, (2) inverting synthetic maps of apparent attenuation obtained by assuming the amplitudes are only affected by focusing and using the elastic phase velocity model of Trampert and Woodhouse (1995), and (3) inverting the observed amplitude data set for Q_R after correcting for focusing. In these experiments, a degree-20 model of 3D apparent attenuation was obtained. They concluded that at the longer periods (e.g., 146 s), the amplitude signal is not severely affected by focusing, whereas at the shorter periods (e.g., 73 s), the contaminating effect is stronger. Also, Selby and Woodhouse (2000) found that low-degree attenuation structure (up to degree 8 in a spherical harmonics expansion) is not significantly affected by focusing in the entire period range considered. In a subsequent study, they inverted the maps of $Q_R(\omega)$ with and without corrections for focusing to obtain a series of models of lateral variations in attenuation in the upper mantle up to degree 8 (Selby and Woodhouse, 2002). In the latter study, they also considered the effect of uncertainties in the source term and found that a frequency-dependent correction factor is necessary to combine the $Q_R(\omega)$ maps into a successful depth-dependent model of attenuation. They concluded that the details of focusing and source corrections did not affect the robustness of their models up to degree 8, but would be more important at shorter wavelengths.

1.25.6.1.3 Current status

An important result of the Selby and Woodhouse studies was the confirmation that surface-wave amplitudes contained information not only on anelastic structure but also on elastic structure that could be exploited, as already suggested by Woodhouse and Wong (1986) and Wong (1989). At about the same time, Billien and Lévêque (2000) made the first attempt at inverting simultaneously Rayleigh-wave amplitude and phase data, for maps of phase velocity and Q_R between 40 and 150 s. The effects of focusing were included using eqn [7], which allowed them to consider shorter periods and shorter wavelengths. The maps obtained at short periods indicate significant correlation between phase velocity and attenuation, and therefore, tectonics and the even-degree part (degrees 2, 4, and 6) of their longer-period maps are compatible with those of other studies. However, their odd-degree part is dominated by degree 5, a feature not found in other studies.

In a recent study, Dalton and Ekström (2006a,b) considered a large global data set of Rayleigh-wave amplitudes in the period range 50–250 s. They inverted this data set, simultaneously, for maps of lateral variations in phase velocity up to spherical harmonics degree 20, attenuation up to degree 12, as well as source and receiver correction factors. As in previous

studies, the focusing effect is also included using expression [7]. A notable result of their study is the high-quality phase velocity maps that they were able to obtain by using only the amplitude constraints in their inversion (Dalton and Ekström, 2006b). Inclusion of the source and receiver correction factors was also found to improve the attenuation mapping. They constructed maps of Rayleigh-wave attenuation at different periods and also found a good correlation of the Q^{-1} distribution with tectonics for periods sensitive to the first 250 km of the upper mantle (Dalton and Ekström, 2006a).

The studies described so far considered only fundamental-mode surface waves, which, in practice, limits the resolution in depth to the top 300–400 km of the upper mantle, even though some attempts at interpreting deeper structure were shown. These studies also used a two-step approach, and often only the results of the first step, inverting for maps of lateral variations of $Q_R(\omega)$ at different periods, were presented (e.g., Billien and Lévêque, 2000; Dalton and Ekström, 2006a; Romanowicz, 1990). The more recent 3D attenuation models include both even and odd terms of lateral heterogeneity in Q_μ (Dalton et al., 2008; Romanowicz, 1995; Selby and Woodhouse, 2002) or in Q_R (Dalton and Ekström, 2006a). **Figure 6** compares maps of Q^{-1} at a depth of ~150 km obtained in different recent studies and shows that while details are still variable from model to model, the large-scale features, with high Q in shield areas low Q under ridges and back arcs, are quite consistent.

In order to improve the depth resolution in the transition zone, it is desirable to develop a methodology that includes information from surface-wave overtones, as well as Love waves. Because overtones are not easily separable due to their similar group velocities, a waveform methodology is desirable. Such a methodology uses a comparison of observed and synthetic seismograms in the time domain. The synthetics can be computed using normal mode theory, taking into account 3D effects at various degrees of approximation. However, to obtain accurate amplitude information from surface-wave data, it is necessary to employ an approach based on the measurement of envelopes or to first align the phase of waveforms before comparing observed and synthetic waveforms. Following these considerations, Gung and Romanowicz (2004) recently developed an iterative waveform inversion approach, in which a large global data set of three-component fundamental and overtone waveforms, filtered in the frequency range 80–250 s, is first inverted for elastic 3D structure, using the nonlinear asymptotic coupling theory approach developed by Li and Romanowicz (1995), up to spherical harmonics degree 24. Different elastic models are computed for Love and Rayleigh waves, to account for the strong radially anisotropic signal in the uppermost mantle (e.g., Ekström and Dziewonski, 1997; Gung et al., 2003; Montagner and Tanimoto, 1991). In a second step, the waveforms, corrected for the 3D elastic structure obtained in the previous step, are inverted for lateral variations of $Q_\mu(r)$ in the upper mantle, up to degree 8. In this process, the waveforms are directly inverted for depth dependence in elastic and anelastic structure.

Although Gung and Romanowicz (2004) did not include focusing effects in deriving their model QRLW8, subsequent tests indicated that the model was robust with respect to these effects, in agreement with the predictions of Selby and Woodhouse (2000). In particular, Gung and Romanowicz (2004) compared the degree-8 $Q_\mu(r)$ model obtained with and without focusing terms, the latter computed using expression [8] in the 3D elastic model obtained in the first step, and found no significant changes. Including focusing in the second step of the inversion justifies inverting for a higher-degree Q_μ model. **Figure 7** shows a comparison of the models obtained

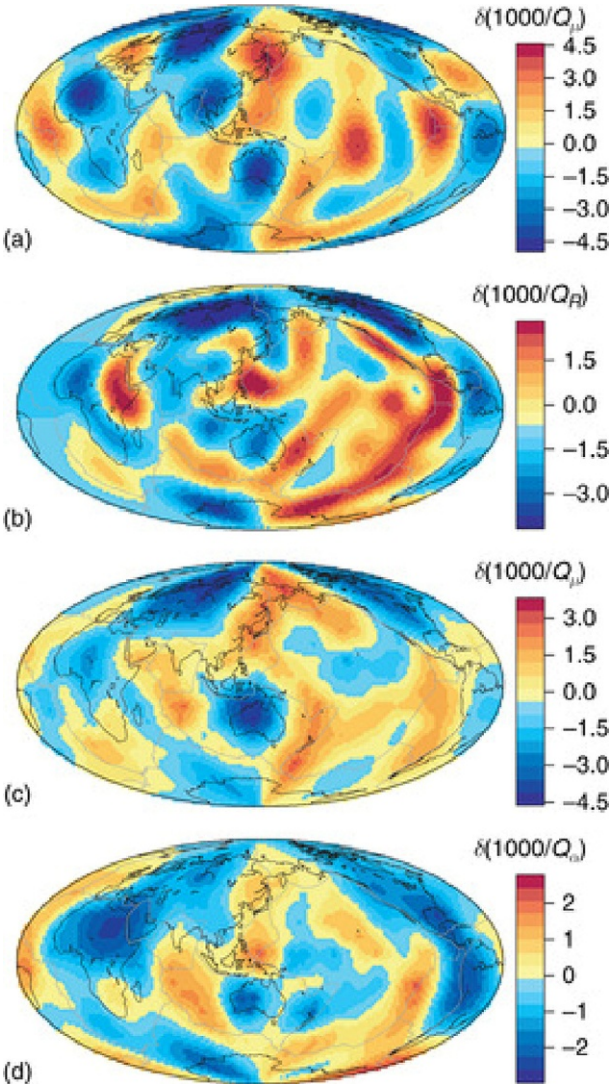

Figure 6 Comparison of global Q models in the uppermost mantle. (a) QRLW8 model (Gung and Romanowicz, 2004), from inversion of three-component surface-wave and overtone waveform data, presented is Q_μ at a depth of 160 km. (b) Map at 150 km of the Rayleigh-wave-based Q model QRFS12 of Dalton et al. (2008). (c) Average Q_μ in the depth range 0–250 km from Selby and Woodhouse (2002) and also from Rayleigh waves. (d) Average variations in Q_α in the first 250 km of the mantle from amplitude ratios of P and PP (Warren and Shearer, 2002). Some of the differences observed may be due to the different depth ranges sampled: in models (a), (c), and (d), the global ridge and back-arc systems all stand out as low Q_μ features, whereas the Atlantic ridge is not as prominent in model (b), while the Red Sea region lights up more strongly. This may be due to the fact that (b) has not been inverted with depth and therefore may include some effects of structure deeper than 250 km.

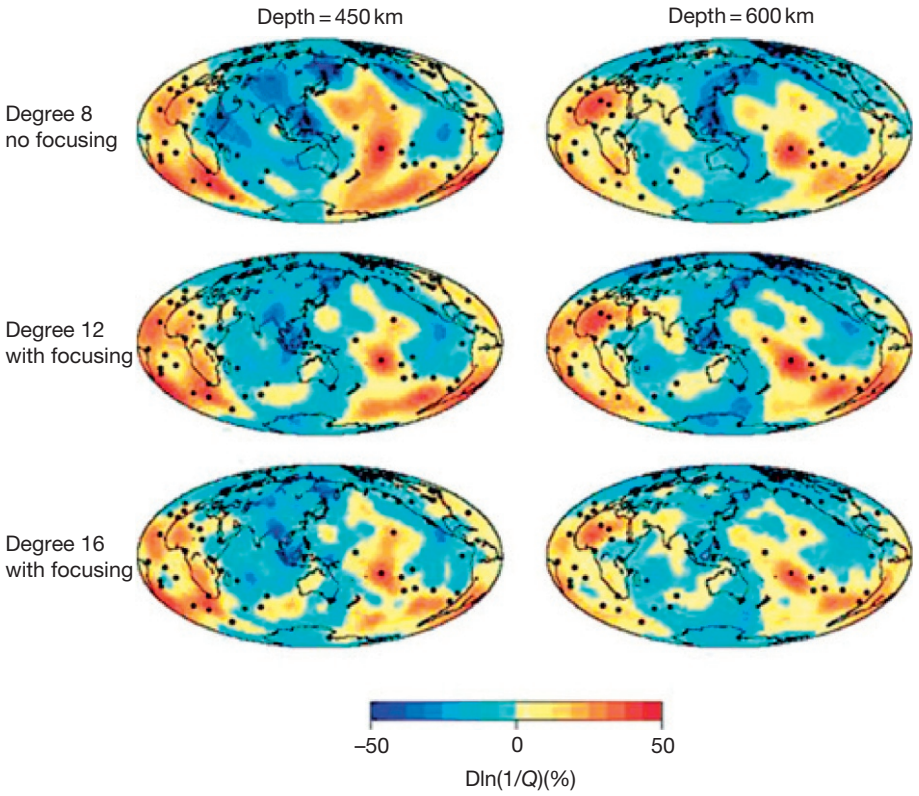

Figure 7 Lateral variations of Q_β in the upper mantle transition zone. (Top) Degree-8 model QRLW8 (Gung and Romanowicz, 2004). In this relatively low-degree model, no corrections for elastic focusing have been included. (Middle/bottom) Inversion of the same three-component long-period seismograms for a degree-12 model (middle) and a degree-16 model (bottom). In both cases, the waveforms have been corrected for focusing effects before inversion, using an asymptotic higher-order formalism (Romanowicz, 1987). The main features of these models, namely, strong low-*Q* anomalies in the South Pacific and under Africa, correlated with the hotspot distribution of Davies (1990) (black dots) and high-*Q* anomalies under the western Pacific, remain stable, but the low-*Q* features sharpen up in the higher-resolution models.

up to degrees 12 and 16, in the transition zone, when focusing terms are included. Clearly, the large-scale features remain stable among the models, with some variability in the details. They indicate that, in contrast to the upper 200–300 km of the mantle, the main features in Q_μ in the transition zone are two large low-Q regions in the south-central Pacific and under Africa, which correlate with the distribution of elastic velocities at the base of the mantle (Romanowicz and Gung, 2002), as well as the distribution of hotspots, confirming earlier results (Romanowicz, 1994b).

The most recent global 3D upper mantle model of Q_μ was developed by Dalton et al. (2008) based on fundamental-mode Rayleigh-wave data using the methodology of Dalton and Ekström (2006b). The resulting model (QRFSI12), expressed to degree 12 in spherical harmonics, takes into account source and station terms as well as focusing effects. It confirms the correlation of Q_μ^{-1} with surface tectonics in the first 200–250 km of the upper mantle (e.g., **Figure 6**) and a shift at greater depth to a structure dominated by high attenuation beneath the central Pacific and Africa and low attenuation in subduction zone regions. Dalton et al. (2009) found strong correlations between attenuation distribution (in model QRFSI12) and shear velocity in different tectonic regions and inferred that lateral variations in temperature of 150–200 °C can explain most of the observed variability in velocity and attenuation in the top 250 km of the upper mantle, except in cratonic regions where compositional differences may be required, in agreement with earlier studies. In particular, inversion of long-period seismic waveforms assuming only lateral variations in temperature results in temperatures in the cratonic upper mantle that are more than 100 °C colder than estimated from heat flow measurements and the analysis of xenoliths (e.g., Cammarano and Romanowicz, 2007). Dalton and Faul (2010) compared the seismological trends to experimental trends in dry olivine samples and concluded that in regions of the upper mantle where the relationship between attenuation and velocity cannot be explained by temperature variations alone, the discrepancies can be explained by a combination of the presence of partial melt (oceans at depths ~100 km) or compositional differences (cratons at depths <250 km), although the composition that would give rise to the observed mismatch in cratons remains elusive.

Some variability in the correlation between velocity and attenuation maps may be due to the effects of anelastic dispersion due to attenuation, as also investigated by Zhou (2009). Assuming a 3D Q model derived from an existing 3D shear velocity model under the assumption that all lateral variations of structure in the upper mantle are due to temperature

variations, Zhou (2009) calculated finite frequency kernels and found that dispersion corrections in the phase due to attenuation are important enough in the period range 50–200 s (up to 25% of the elastic effect) so that they cannot be neglected in global surface-wave tomography.

With the advent of accurate global 3D numerical computations of the seismic wavefield, it has become possible to evaluate more precisely the effects of 3D elastic structure on the amplitudes of long-period surface waveforms and, vice-versa, the effect of 3D Q variations on velocity modeling, through anelastic dispersion. Savage et al. (2010) incorporated attenuation into their spectral element code (Specfem, e.g., Komatitsch et al., 2002) and investigated competing effects on amplitudes due to elastic and anelastic 3D structure at the regional scale. Ruan and Zhou (2010) used the same spectral element method to quantify the effects of 3D Q structure on surface-wave phase delays and found that about 15–20% of the phase delays may be due to 3D Q structure through the mechanism of anelastic dispersion, especially in the period range 60–150 s, less so at longer periods. Using a similar approach, Ruan and Zhou (2012) confirmed, in turn, that the effects of elastic focusing and scattering on surface-wave amplitudes are as important as those of 3D Q and cannot be ignored, even at long periods. Such numerical techniques hold promise for advances in the resolution of Q structure at global and regional scales.

1.25.6.2 Global Body-Wave Studies

In the same way as differential travel times of teleseismic body-wave phases are used to obtain information on the distribution of upper mantle velocities, global-scale lateral variations in attenuation can be inferred from differential amplitude measurements (i.e., amplitude ratios). These measurements are difficult, however, as they are sensitive to the window chosen for each phase, as well as to contamination by complex structure near the source, receiver, and bounce points. Komatitsch et al. (2002) have called attention to the importance of considering the effects of focusing and scattering in the crust. **Chapter 1.06** provides details about the theoretical computation of the effects of attenuation on body waves.

Only three published studies to date have developed models of upper mantle Q based on differential body-wave measurements, two for Q_μ using S phases (Bhattacharyya et al., 1996; Reid et al., 2001) and one for Q_α (Warren and Shearer, 2002). Each of them used slightly different methods, but the basic principle remains the same.

The amplitude spectra of recorded body waves can be expressed as

$$A(\omega) = cS(\omega)R(\omega)I(\omega)A_c(\omega)F(\omega)\exp(-\omega t^*/2) \qquad [12]$$

where c is a constant expressing the radiation pattern and the geometric spreading, $S(\omega)$ is the source spectrum, $R(\omega)$ is the crustal response, $I(\omega)$ is the instrument response, A_c is the crustal layering/reflectivity at the bounce point for reflected waves, F is a hypothetical factor that includes possible effects of focusing, and t^* is defined in eqn [5]. In body-wave studies, the frequency dependence of Q needs to be taken into account, because the measurements are performed at higher frequency (typically 0.15–1 Hz for P waves and 0.05–0.1 Hz for S waves), closer to the high-frequency cutoff in the Earth's absorption band. The frequency dependence of Q is often expressed in terms of an absorption band model (eqn [2]). However, Warren and Shearer (2002) estimated the effect of frequency dependence on the attenuation of P waves around a period of 1 s and concluded that neglecting it did not significantly bias their measurements of lateral variations in Q_α. On the other hand, Reid et al. (2001) suggested that the frequency dependence might be absorbed in the source terms.

Pairs of phases (1,2) are selected so as to eliminate as many factors as possible from their spectral amplitude ratio. The differential δt^* can then be obtained by measuring the slope of the remaining spectral ratio as a function of frequency:

$$\ln(A_2/A_1) = -\omega/2(\delta t^*) + \varepsilon \qquad [13]$$

where $\delta t^* = t_2^* - t_1^*$ and ε is a constant containing the effects of differential radiation pattern, geometric spreading, and focusing for the two phases. The assumption of frequency independence needs to be verified even if dispersion corrections have been applied, and this is usually done by checking the linearity of the slope, as well as the constancy of the phase of the complex spectral ratio.

Because the lateral variations of Q in the lower mantle are thought to be much smaller than in the upper mantle, the differential t^* thus obtained is attributed to lateral variations of structure in the upper mantle under the bounce point of the reflected phase. Given the steep approach of the reflected rays at the bounce point and the relatively sparse global sampling, these measurements provide information about the average upper mantle lateral variations in Q but have little depth resolution.

This general principle of slope measurement was used by Bhattacharyya et al. (1996) and Warren and Shearer (2002). However, these authors used different approaches to correct for potential receiver and source biases. Bhattacharyya et al. (1996) considered the spectra of S and SS from the same records, in the distance range 40–120° and the period range 15–25 s, and then estimated the differential t^* by applying a multiple-record stacking technique, grouping the records by bounce point location, and assuming that effects of source, receiver, and path, outside of the common upper mantle path of the SS waves with common bounce location, would average out in the stacks. The bounce point location area over which the stacking was performed was caps of 5° radius, larger than the estimated Fresnel zones of the corresponding reflected waves. These authors used a frequency domain multitaper technique to minimize the effects of finite source duration and near-source or near-receiver structure complexity. They found a correspondence between the cap-averaged t^* and tectonic provinces, with, as expected, lowest attenuation under platforms and shields and highest attenuation under young oceans. In a second step, they inverted for a depth-dependent model of Q_μ in the upper mantle, expanded laterally up to degree 8 in spherical harmonics, and assuming three layers in depth (20–220, 220–400, and 400–670 km). Resolution experiments indicated that the best resolved layer was the deepest one, and the two shallower ones could not be distinguished uniquely.

Warren and Shearer (2002), on the other hand, considered independent data sets of P waveforms, in the distance range 40–80°, and PP waveforms in the distance range 80–160°.

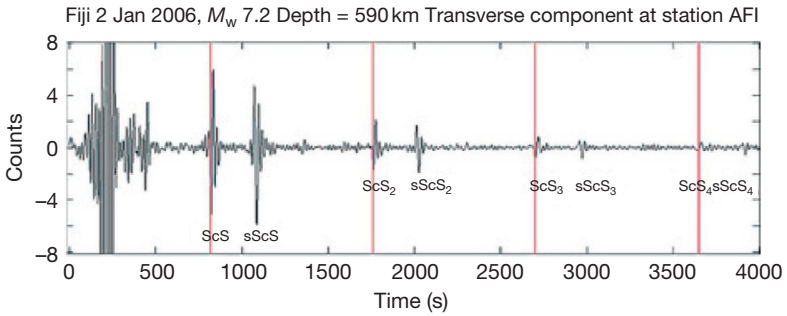

Figure 8 Example of multiple ScS record for a deep earthquake in the Fiji Islands, showing clear multiples out to ScS_4, as well as their depth phases. Courtesy of Ved Lekic.

Working in the frequency domain, they first determined source and receiver terms for the P data set, using an iterative stacking procedure over common sources and common receivers. Then they assumed that the same source and receiver terms could be applied to the PP phases, since the two phases have similar takeoff angles, path lengths, and turning depths, given the distance ranges considered. They thus corrected the PP amplitude spectra using the source and receiver terms determined from the P spectra and estimated the residual t^* attributed to the upper mantle beneath the bounce point. Finally, to reduce the scatter in the data, they estimated cap averages over nonoverlapping bounce point areas of 5° radius. They too found the highest Q_α (smallest t^*) under shields and platforms and the lowest Q_α (largest t^*) under young oceans (e.g., **Figure 6**). Unlike Bhattacharyya et al. (1996), these authors considered, however, that their measurements reflected the average structure over the top 220 km of the mantle and derived the corresponding Q_α averaged over that depth range.

Reid et al. (2001) developed a somewhat different method, based on waveform fitting, which they applied to a large data set of SS and S waveforms from seismograms collected in the distance range 50–105° and also to SSS and SS, in the distance range 90–179°. In the process, they included the effects of elastic structure on differential travel times of these phases. These authors considered that their data had sensitivity down to 400 km and inverted their t^* data set for a model of Q_μ expanded laterally to degree 8 and in depth, using a spline parametrization with six knots. However, their resolution tests indicated that the depth resolution was poor and that they could not attribute the lateral variations found to a particular depth.

The most recent attempt at using body-wave phases to constrain 3D Q_μ variations at the global scale is a study that includes differential attenuation measurements between S and a combination of upper and lower mantle-sensitive multiple phases (ScS, SS, and corresponding depth phases; Lawrence and Wysession, 2006b). These authors validate their model in the upper mantle against model QRLW8 (Gung and Romanowicz, 2004), arguing that the qualitative similarities imply robustness of their lower mantle model. The most striking feature of their lower mantle model is a large low-*Q* region in the depth range 700–1400 km beneath the subduction zones in eastern Asia, which they attribute to the presence of water. However, the authors do not evaluate or make any corrections for elastic contaminating effects in this highly heterogeneous region, which makes their model tentative until confirmed by future independent studies.

1.25.6.3 Body-Wave Studies of Regional Extent

1.25.6.3.1 Multiple ScS studies

Although they do not provide a complete global coverage, the most widely used shear-wave phases for large-scale regional mantle attenuation studies have been multiple ScS phases. Measurements of the attenuation of these near-vertical multiply reflected waves are relatively uncontaminated by source, instrument, and geometric spreading effects. They and their depth phases appear very clearly on transverse seismograms in the 'reverberative interval,' after the first arriving surface-wave train (**Figure 8**). In the absence of noise, the spectral domain transfer function relating ScS_n to ScS_{n+1} is

$$H(\omega) = \exp[-\omega T_0/2Q(\omega)]\cdot\exp[i\theta(\omega, T_0)] \qquad [14]$$

where T_0 is the differential travel time between the two phases, θ is a phase function, and $Q(\omega)$ is the quality factor, which is an estimate of the vertically averaged attenuation through the mantle. As in the case of other differential measurements, the estimate of Q_{ScS} is obtained by measuring the slope of the amplitude of the transfer function as a function of frequency. The stability of the phase spectrum is used as an additional indication of the quality of the measurement.

Early studies used spectral ratios measured on hand-digitized and hand-rotated transverse component seismograms and provided evidence for large amplitude lateral variations of Q_{ScS} in the mantle (e.g., Kovach and Anderson, 1964; Press, 1956; Sato and Espinosa, 1967; Yoshida and Tsujiura, 1975). Because of the analog records used, and the measurement methods employed, which did not take into consideration the biasing effects of noise, these early estimates are considered to be less accurate than more recent ones. They are also generally biased toward very high values of Q_{ScS}, compared to normal mode results, which has been attributed not only to the effects of noise but also, potentially, to the effect of frequency dependence of *Q*, as the instruments that produced the records had limited bandwidth. With the advent of digital long-period instrumentation, and the development of more sophisticated methods that were better suited for minimizing the effects of noise (e.g., Jordan and Sipkin, 1977; Nakanishi, 1979a), measurements became more accurate. For example, Jordan and Sipkin (1977) introduced a method of phase equalization, by computing cross correlation between successive ScS multiples, as well as stacking to reduce measurement scatter. Nakanishi (1979a) used a maximum likelihood method to reduce the

effects of noise. Most measurements are performed in the frequency band between 10 and 40–60 MHz, where frequency dependence of Q_{ScS} has been found to be negligible (e.g., Sipkin and Jordan, 1979). These studies have confirmed the existence of large lateral variations in Q_{ScS} (e.g., Chan and Der, 1988; Gomer and Okal, 2003; Lay and Wallace, 1983, 1988; Revenaugh and Jordan, 1989, 1991; Sipkin and Jordan, 1980; Sipkin and Revenaugh, 1994; Suetsugu, 2001). The derived average mantle values for $Q_\mu \sim 220$–240 are, in general, compatible with those obtained from normal modes.

Measurements under oceans and in the vicinity of subduction zones are more numerous, because of the availability of deep earthquakes and the relatively simple effects of the thin crust at the surface reflection points. Measurements under continents are more difficult, because the effect of crustal multiples at the surface reflection point needs to be taken into account (e.g., Isse and Nakanishi, 1997; Sipkin and Revenaugh, 1994). In order to expand the coverage under continents, it is also necessary to consider shallow earthquakes, for which the reverberation interval is more noisy because of the presence of strong multipathing surface waves.

These studies determined that, on average, Q_{ScS} is higher under continents than under ocean basins. Regional variability on relatively short scales has been found in subduction zone regions. In particular, low Q was estimated under the Sea of Japan (e.g., $Q_{ScS} \sim 160$; Nakanishi, 1979a) and under northern South America ($Q_{ScS} \sim 93$; Lay and Wallace, 1983), in regions sampling the upper mantle wedge and/or back-arc region behind subduction zones, which, if primarily attributed to the upper mantle, translates into very low Q. On the other hand, high Q values comparable to continental estimates were obtained on path sampling through slabs (e.g., $Q_{ScS} \sim 232$, in South America, Lay and Wallace (1983); $Q_{ScS} \sim 226$, under Japan/Kuriles, Nakanishi (1979a); and $Q_{ScS} \sim 266 \pm 57$ in Argentina, Sipkin and Jordan (1980)). These older measurements are generally in agreement with a more recent study by Chan and Der (1988), except in the southwest Pacific, where these authors found $Q_{ScS} \sim 214 \pm 42$ compared to the estimate of $Q_{ScS} \sim 157 \pm 17$ (Sipkin and Jordan, 1980). This may however be due to the way the latter averaged their measurements over an extended region where strong lateral variations in Q_{ScS} have since been confirmed (Gomer and Okal, 2003; Suetsugu, 2001). Using short epicentral distance data ($<20°$) filtered between 10 and 50 MHz, Suetsugu (2001) found very low Q under the South Pacific superswell ($Q_{ScS} \sim 70$–80), whereas Gomer and Okal (2003) found very high Q under the Ontong Java Plateau, also using short distances (10–20°) and a bandpass between 10 and 62.5 MHz.

The lateral variations found in Q_{ScS} are attributed primarily to the upper mantle, because of the much higher Q in the lower mantle, which reduces the effects on multiple ScS of any, even significant, lateral variations (e.g., Warren and Shearer, 2002) and the significant correlation of Q_{ScS} with tectonics. Furthermore, the correlation with travel time anomalies from the same multiple ScS phases suggests that they could be primarily related to lateral variations in temperature.

Caution must be exercised, of course, in attributing all of the Q_{ScS} signals to the upper mantle, in particular if there is a low-Q zone at the base of the mantle (e.g., Revenaugh and Jordan, 1991) and significant lateral variations of Q in D″. While attenuation in D″ and its variations have yet to be explored at the global scale, the presence of large variations in velocity implies that at least some lateral variations exist in Q as well. Recently, Fisher and Wysession (2003) showed evidence for the existence of an ~600 km wide high-attenuation, low-velocity region in D″ beneath Central America, using spectral ratios of S and ScS phases.

1.25.6.3.2 Body-wave attenuation studies in North America

A few recent studies have taken advantage of the large quantity of broadband data available over North America to estimate lateral variations in attenuation across the continent, using surface waves (Lawrence et al., 2006) or body waves (Hwang et al., 2009, 2011). In agreement with global studies and early studies (e.g., Der et al., 1982; Solomon and Toksöz, 1970), these studies generally find large-scale lateral variations correlated with tectonics. More such studies are forthcoming, with the growing database from the EarthScope USArray program.

1.25.6.3.3 Body-wave studies of upper mantle Q around subduction zones

High attenuation has been reported in the back of island arcs using other types of body waves (e.g., Wiens et al., 2008). Early estimates were very qualitative (e.g., Barazangi and Isaaks, 1971; Barazangi et al., 1975; Bowman, 1988). This was confirmed by several regional studies (e.g., Flanagan and Wiens, 1990, 1994; Roth et al., 1999, 2000) that utilized shear depth phases from deep earthquakes observed teleseismically or at regional arrays to obtain constraints on the attenuation in the upper mantle wedge above different subduction zones. Flanagan and Wiens (1990) measured differential attenuation between sS–S and sScS–ScS phase pairs beneath the Lau back-arc spreading center in the Fiji–Tonga region. Studying the variation of the estimated Q as a function of depth of the source, they found high attenuation in the first 200–300 km and decreasing attenuation at greater depth. They found very high attenuation ($Q \sim 20$–35) in the uppermost mantle beneath the spreading center and somewhat lower attenuation ($Q \sim 50$) beneath older parts of the Lau Basin. Flanagan and Wiens (1994) extended this approach to the study of several inactive back-arc basins in the western Pacific and confirmed the presence of high attenuation ($Q \sim 40$–50) in the uppermost mantle (depths <160 km), with even lower Qs (<40) in the vicinity of the volcanic centers. They also confirmed a systematic increase of Q with depth ($Q \sim 115$ between 160 and 430 km and $Q \sim 173$ in the transition zone). The frequency band of these two studies was 10–80 MHz.

Following the method of Teng (1968), Roth et al. (1999) assembled a data set of differential S–P and P–P attenuation measurements from a temporary local array of broadband land and ocean bottom stations in the Tonga–Fiji region. The data set they assembled allowed them higher resolution compared to teleseismic data because of the geometry of the source-station distribution, the short paths, and the small Fresnel zones compared to teleseismic phases. These authors measured δt from spectral ratios and obtained an estimate of the best fitting Q_α/Q_β ratio as part of the inversion for Q_α and Q_β, assuming that Q is not frequency-dependent in the

band-pass of their study (0.1–3.5 Hz), which seems to be verified by the data. They confirmed the high-attenuation values in the uppermost mantle found previously beneath the spreading center. In their model, the slab appears as a high-Q zone ($Q_\alpha > 900$) down to at least 400 km, below which it is indistinguishable from the surrounding mantle. An abrupt transition from the high-Q slab to the low-Q back-arc basin occurs approximately at the Tonga volcanic front. The lowest Q_α values (~ 90) are found directly under the Lau back-arc spreading center. There is also evidence for a north–south trend, with attenuation on average higher by 10% in the northern part of the region. This Q tomographic model correlates well with velocity models in the region. The best fitting Q_α/Q_β ratio is ~ 1.75, which is in agreement with a loss in bulk about 1/3 that of the loss in shear, assuming a Poisson solid (**Figure 9**).

A similar study under the northern Philippine Sea, this time using only S–P spectral ratios (Shito and Shibutan, 2003b), also found high Q in the Philippine and Izu–Bonin slabs and low Q under the spreading center in the Shikoku Basin. However, the lowest values of Q were found at larger depths (250 km) than in the Lau Basin. The authors attributed that to the older age of the Shikoku spreading center. Several other studies in the last decade have investigated different subduction zones and confirmed the presence of strong lateral variations in Q, with lowest values under volcanic centers (as low as $Q_\mu = 40$ at 1 Hz in some areas) and an order of magnitude higher in the slab. These studies have used local earthquake data in Japan (Nakajima and Hasegawa, 2003; Takanami et al., 2000; Tsumura et al., 2000), in New Zealand (Eberhart-Phillips and Chadwick, 2002), in the Andes (Haberland and Rietbrock, 2001; Myers et al., 1998; Schurr et al., 2003), in Alaska (Stachnik et al., 2004), and more recently in Central America (Rychert et al., 2008), and in the Marianas (Pozgay et al., 2009). The recent studies have investigated frequency dependence in Q and, in some cases, have attempted to constrain attenuation in bulk, from Q_P/Q_s ratios. Frequency dependence appears to be in agreement with laboratory measurements ($\alpha \sim 0.1$–0.3), while the amount of attenuation in bulk is not yet very well constrained, reaching 30% of the value of attenuation in shear in some cases (e.g., Roth et al., 2000), but not required at all in some other studies (e.g., Pozgay et al.,

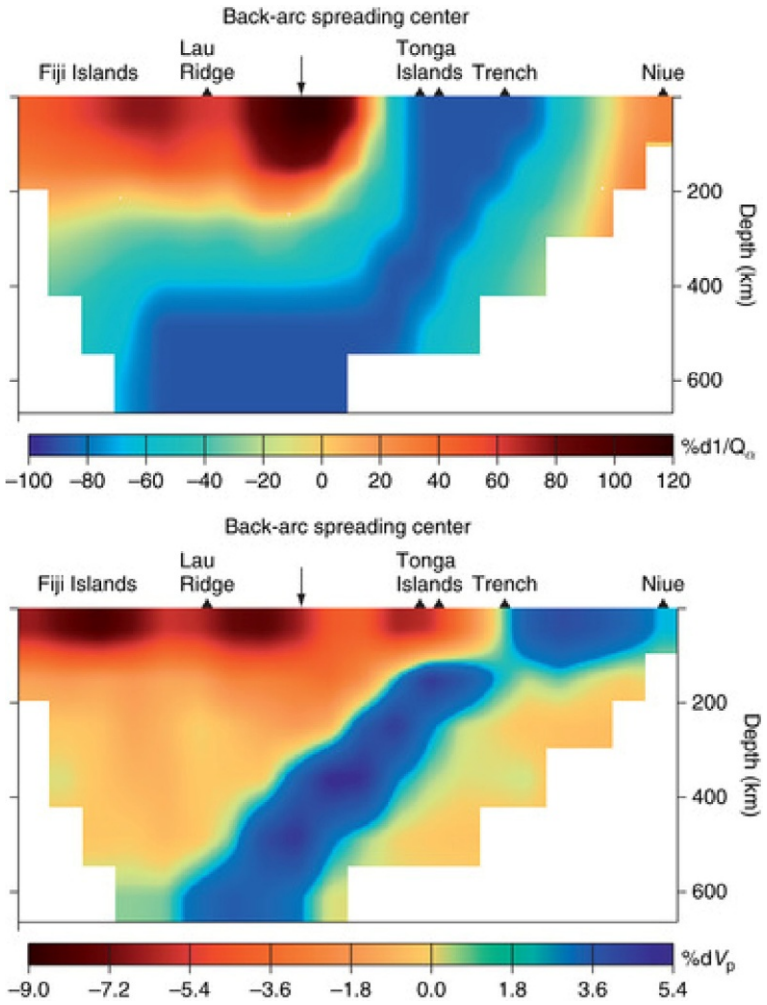

Figure 9 Cross section illustrating lateral variations of structure in the Lau back-arc basin. (Top) Attenuation. (Bottom) Velocity (V_p). Reproduced from Roth E, Wiens DA, and Zhao D (2000) An empirical relationship between seismic attenuation and velocity anomalies in the upper mantle. *Geophysical Research Letters* 27: 601–604.

2009). There may be a suggestion of the need for bulk attenuation only in the slab and not in the wedge (Stachnik et al., 2004). Further high-resolution studies are needed to more clearly separate the effect of frequency dependence from that of bulk attenuation.

1.25.6.3.4 Regional studies of upper mantle Q in mid-oceanic settings

Just as the upper mantle is found to be highly attenuating under back-arc spreading centers, other studies have investigated mid-ocean ridge systems and found very low *Q* (Ding and Grand, 1993; Molnar and Oliver, 1969; Sheehan and Solomon, 1992; Solomon, 1973). Sheehan and Solomon (1992) used the pair of teleseismic phases S and SS along the North Atlantic ridge and found that SS–S differential attenuation decreases with increasing age of the oceanic plate and that, in order for their measurements to be compatible with surface-wave studies, the high-attenuation region must extend into the asthenosphere. Ding and Grand (1993) performed waveform modeling of multiple S phases (up to S_4) at distances between 30° and 80° along the East Pacific Rise. Because their data have sensitivity to the deep mantle, they found that, in order for their measurements to be compatible with multiple ScS results, a significantly lower average *Q* in the lower mantle is needed than obtained from normal mode measurements, indicating that lateral variations in *Q* may also exist in the lower mantle. Note that Sipkin and Jordan attributed a lower *Q* in the Fiji–KIP corridor from multiple ScS measurements to frequency dependence. In the light of the Ding and Grand (1993) study, it seems more likely that the observations of Sipkin and Jordan (1979) could just be due to lower *Q*s in the lower mantle, especially as both studies sampled regions of the Pacific superplume. Strong lateral variations in the lower or lowermost mantle would need to be invoked to reconcile these results with the recent 1D mantle *Q* models constructed using body-wave data of similar frequencies, which exhibit high *Q*s in the lower mantle (e.g., **Figure 4**).

In the last decade, there have been increasing efforts to interpret tomographic models of the upper mantle at various scales in terms of temperature, degrees of partial melt, water content, and rock composition, using constraints from elastic and anelastic tomography, heat flow, gravity, and experimental data. Thus, Sobolev et al. (1996) found that the Massif Central in France is underlain by a hot mantle body with a potential temperature 100–200 °C higher than the upper mantle average. In an interpretation of velocity and *Q* tomography under the Philippine Sea, Shito and Shibutan (2003a) found that the deeper upper mantle (300–400 km depth) may contain 10–50 times more water than average. Boyd and Sheehan (2005) measured differential t^* of S-phase waveforms from the Rocky Mountain Front broadband network and found a north–south zone of very low Q_μ in the upper mantle beneath the Rocky Mountains. Combining attenuation and velocity data, they inferred that the Colorado Rocky Mountains are supported by low-density mantle and a thick crust. On the other hand, comparing their laboratory measurements of Q_μ with global seismological *Q* models, Faul and Jackson (2005) inferred that the upper mantle low-velocity zone could be explained by solid-state processes, without invoking partial melting. Lawrence et al. (2006) applied a waveform cross-correlation method and cluster analysis to the study of upper mantle P- and S-wave attenuation across the North American continent and found that the distribution of attenuation is in general correlated with that of velocity, implying higher temperatures beneath the western tectonic regions than under the more stable east, in agreement with both global and crustal continental-scale studies.

In general, t^* measurements and surface-wave attenuation measurements are interpreted in terms of anelastic attenuation; however, contributions from scattering can be important and need to be considered. For example, in a study of S-wave amplitude variations under Iceland, Allen et al. (1999) found that the low-velocity cylindrical-shaped plume acts as a lens, causing frequency-dependent focusing that dominates over anelastic effects on the amplitudes.

A somewhat puzzling result is that of Yang et al. (2007), who, for the first time, measured attenuation of surface waves in the vicinity of the East Pacific Rise, from a regional ocean bottom network. From a joint inversion for velocity and attenuation, taking into account elastic effects on the amplitudes to some degree, these authors found surprisingly lower attenuation than expected under the youngest ocean (Q_μ not less than 90, which is higher than the global average estimates), while elastic velocities are very low. These results are not compatible with a purely thermal model of attenuation (e.g., Faul and Jackson, 2005) nor with results from back-arc spreading centers in Mariana and Tonga/Lau (e.g., Pozgay et al., 2009). The authors suggest that the presence of water might be partially responsible for the drop in velocity, through the anelastic attenuation effect, and that some partial melting may be present beneath the youngest seafloor. However, this would require the absorption peak to be outside of the seismic frequency band. Reconciling these results with those in back arcs and global averages will necessitate further studies that more accurately take into account the elastic effects on amplitudes.

1.25.7 Regional *Q* Variations in the Crust and Uppermost Mantle

1.25.7.1 Introduction

One of the most interesting aspects of *Q* in the crystalline crust and upper mantle of the Earth is the large magnitude of its variation from region to region. Whereas broad-scale seismic velocities vary laterally at those depths by at most 10–15%, *Q* can vary by an order of magnitude or more. **Figure 10** illustrates the large effect that regional *Q* variations can have on phases that travel through both the upper mantle (P and S waves) and the crust (Lg) by comparing records for paths across the eastern and western United States. Since variations in *Q* can be so large, seismic-wave attenuation is often able to relate *Q* variations to variations in geologic and geophysical properties that are not easily detected by measurements of seismic velocities. Factors known to contribute to *Q* variations in the crust and upper mantle include temperature and interstitial fluids.

In this section, we will emphasize studies of *Q* variation conducted over regions sufficiently broad to contribute to our knowledge of crust and upper mantle structure and evolution. In so doing, we neglect many studies that have provided useful information on crustal *Q* over small regions.

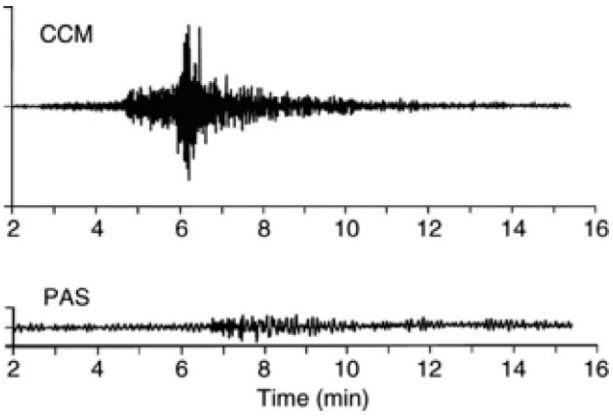

Figure 10 Seismograms recorded at stations CCM (Cathedral Cave, MO) and PAS (Pasadena, CA) for the m_b 4.5 event in southeastern New Mexico that occurred on 2 January 1992 at 11:45:35.6 UT. The epicentral distance to CCM (along a relatively high-*Q* path) is 1256 km and to PAS (along a relatively low-*Q* path) is 1417 km. Reproduced from Mitchell BJ (1995) Anelastic structure and evolution of the continental crust and upper mantle from seismic surface wave attenuation. *Reviews of Geophysics* 33: 441–462.

1.25.7.2 *Q* or Attenuation Determinations for Seismic Waves in the Crust

Investigators have employed different methods, phases, and frequency ranges to study the anelastic properties of the crust and upper mantle. At higher frequencies and shorter distances often employed for crustal studies, some researchers have emphasized determinations of intrinsic Q (Q_i), some have emphasized the scattering contribution (Q_s), and some have sought to determine the relative contributions of Q_i and Q_s. The importance of scattering became apparent from the groundbreaking work of Aki (1969) who first showed that the codae of various regional phases are composed of scattered waves. His work spawned a large literature on both theoretical and observational aspects of scattering that is discussed in Chapter 1.24.

The contributions of the intrinsic and scattering components to total attenuation, $1/Q_t$, can be described by

$$\frac{1}{Q_t} = \frac{1}{Q_i} + \frac{1}{Q_s} \qquad [15]$$

where Q_i and Q_s refer, respectively, to intrinsic Q and scattering Q (Dainty, 1981). Richards and Menke (1983) verified that the contributions of intrinsic and scattering attenuation are approximately additive as described by eqn [15]. Seismologists often wish to focus on Earth's intrinsic anelastic structure. To do so, they must select a phase or work in a frequency range such that the effect of scattering can either be determined or is small relative to the effect of intrinsic Q.

This chapter almost entirely addresses intrinsic Q, but we will discuss one type of scattered wave (Lg coda) quite extensively. Although Lg coda is thought to contain a large amount of scattered energy, some theoretical and computational studies (discussed later) of scattered S-wave energy suggest that measured Q values for that wave may largely reflect intrinsic properties of the crust.

All of the measurements that we discuss in this section can be placed in one of two major categories: (1) those in which seismic source effects cancel and (2) those in which assumptions are made about the seismic source spectrum. For category (1), the cancellation is most often achieved by using ratios of amplitudes recorded by two or more instruments. But it has also been achieved using ratios of amplitudes from different portions of a single time series. The primary application of the latter type of cancellation has been for the determination of Lg coda Q (Q_{Lg}^{C}). We divide this category into three parts that address regional phases, fundamental-mode surface waves, and Lg coda. Category (2) permits studies of Q using a single station but requires knowledge of the source depth, source mechanism, and velocity model for the source region. We divide this category into two parts, one addressing regional phases and the other fundamental-mode surface waves.

Seismologists have measured the dispersion of body waves due to anelasticity and have successfully used that dispersion to infer values for body-wave Q. We will not cover that topic because it has been the subject of relatively few studies and has been applied mainly to small regions.

The following subsections discuss methodology and present some representative results using the cited methods as applied to the crust. Because the number of studies for continents is overwhelmingly greater than for oceans, most of the discussion will pertain to continental regions. A few studies will, however, be described for oceanic regions.

1.25.7.2.1 Spectral decay methods in which source effects cancel: regional phases

Regional phases include P, S, and Lg phases recorded at distances less than about 1000 km. The early portion of this section mostly covers Q determinations for P and S phases, but in cases where researchers measured Q_{Lg}, as well as Q_P and Q_S, all results will be presented. The latter part of this subsection will discuss Lg exclusively since this phase has been widely used in recent years to study variations of Q over broad regions.

In order to cancel source effects, several methods utilize stations that lie on a common great-circle path with the seismic source, but other methods are able to dispense with the need for great-circle path propagation. All studies, however, need to first remove the effect of wave-front spreading before measuring amplitude changes due to attenuation. In this subsection, we will restrict our discussion to studies at frequencies that pertain totally or predominantly to the crust with occasional reference to the upper mantle for studies that include results for both the crust and upper mantle.

Regional and near-distance studies of P- and S-wave attenuation (or their respective quality factors Q_P and Q_S) often cancel the source by utilizing several stations at varying distances (e.g., Carpenter and Sanford, 1985; Nuttli, 1978, 1980; Thouvenot, 1983).

More recently, amplitude measurements in which both the source and sensor reside in boreholes beneath any sediments or weathered layers have provided much-improved estimates of Q_P and Q_S. Abercrombie (1997) used borehole recordings to determine spectral ratios of direct P to S waves and found that they are well modeled with a frequency-independent Q_P distribution in the borehole increasing from $Q_P \sim 26$–133 at depths between the upper 300 m and 1.5–3 km. Q_S increased

from 15 to 47 in the same depth range. Abercrombie (2000), in another borehole study near the San Andreas Fault, found that the rate of attenuation on the northeastern side of the fault is about twice that on the southwestern side.

Lg is very useful for Q studies because it both travels predominantly in the crustal waveguide, providing Q information for a known depth interval, and is a large and easily recognizable phase. Even relatively small earthquakes can generate useable records; thus, data in many regions are plentiful. Lg can be represented by a superposition of many higher-mode surface waves or by a composite of rays multiply reflected in the crust. It is usually assumed that Q_{Lg} follows a power-law frequency dependence, $Q = Q_0 f^{\eta}$, where Q_0 is the value of Q_{Lg} at a reference frequency and η is the frequency dependence parameter at that frequency. Lg travels through continental crust at velocities between about 3.2 and 3.6 km s^{-1} and is usually followed by a coda of variable duration. That coda is discussed in a later subsection. Since the Lg wave consists of many higher modes, it is often assumed that, even though the radiation patterns for individual modes differ from one another, the totality of modes combines to form a source radiation pattern that is approximately circular. If that assumption is correct, the source and stations need not necessarily line up along the same great-circle path to estimate Q.

Early determinations of Q_{Lg}, after correcting for wavefront spreading, compared observed attenuation with distance with theoretically predicted attenuation for the Lg phase and chose the theoretical curve (predicted by selected values of Q_0 and η), which agreed best with observations (e.g., Bollinger, 1979; Campillo et al., 1985; Chavez and Priestley, 1986; Chun et al., 1987; Hasegawa, 1985; Nuttli, 1973; Street, 1976).

Benz et al. (1997) studied four regions (southern California, the Basin and Range Province, the central United States, and the northeastern United States and southeastern Canada) of North America in the frequency range 0.5–14.0 Hz. They found that, at 1 Hz, Q_{Lg} varies from about 187 in southern California to 1052 in the northeastern United States and southeastern Canada and about 1291 in the central United States. They also found that the frequency dependence of Q also varies regionally, being relatively high ($\alpha \sim 0.55$–0.56) in southern California and the Basin and Range Province and smaller ($\alpha \sim 0$–0.22) in the other three regions.

Xie and Mitchell (1990a) applied a stacking method to many two-station measurements of Q_{Lg} at 1 Hz frequency in the Basin and Range Province. This method, first developed for single-station determinations of Lg coda Q (Q_{Lg}^{C}), will be discussed in the subsection on Lg coda. They found that $Q_{Lg} = (275 \pm 50) f^{(0.5 \pm 0.2)}$ and $Q_{Lg}^{C} = (268 \pm 50) f^{(0.5 \pm 0.2)}$.

Xie et al. (2004) extended the method to multiple pairs of stations in instrument arrays across the Tibetan Plateau. For an array in central Tibet (INDEPTH III), they found very low values for Q_0 (~ 90) that they attributed to very high temperatures and partial melt to the crust. An array in southern Tibet yielded even lower values, ~ 60, for Q_0 in the northern portion of the array but higher values (~ 100) in a central portion and much higher values (>300) in the southernmost portion. Xie et al. (2006) used a two-station method to obtain more than 5000 spectral ratios for 594 interstation paths and obtained Q_0 and η for those paths. They obtained tomographic maps of those values that are described in the subsection on tomographic mapping. With the purpose of obtaining attenuation information in the upper mantle, Xie (2007) studied Pn attenuation beneath the Tibetan Plateau. He obtained Q_0 and η and studied its regional variation across several regions. He found Q_0 to be highest (374, with η being 0.3) in easternmost Tibet and lowest (188 with η being 0.3) in northern Tibet. The high values for Q_0 are comparable to those reported earlier for central Asia. He found regional Pn attenuation varies inversely with Pn velocity.

1.25.7.2.2 Spectral decay methods in which source effects cancel: fundamental-mode surface waves

When using fundamental-mode surface waves to study lateral variations of crustal Q_{μ}, we need to measure the attenuation of relatively short-period (5–100 s) amplitudes. In continents, these waves may be biased by systematic errors associated with laterally varying elastic properties along the path of travel, as discussed earlier. Two-station studies of fundamental-mode surface waves are especially susceptible to these types of error because researchers might incorrectly assume great-circle propagation along a path through the source and the two stations. Non-great-circle propagation would mean that surface-wave energy arriving at two stations along different great-circle paths could originate at different portions of the source radiation pattern. If that pattern is not circular, the two-station method can produce attenuation coefficient values that are either too high or too low, depending on the points of the radiation pattern at which the waves originate.

To determine surface-wave attenuation, measurements for the situation in which a source and two stations lie approximately on the same great-circle path have often been used to determine surface-wave attenuation. The method was described by Tsai and Aki (1969) and determines the average surface-wave Q between the two stations after correcting for the different wavefront spreading factors at the two stations. They applied the method to many two-station paths from the Parkfield, California, earthquake on 28 June 1966 and, using the formulation of Anderson et al. (1965), obtained a frequency-independent model of intrinsic shear-wave Q (Q_{μ}) with a low-Q zone that coincided with the Gutenberg low-velocity zone in the upper mantle. Love-wave Q was greater than 800, and Rayleigh-wave Q was greater than 1000 in the period range 20–25 s.

Other studies using that method to obtain Q_{μ} models at crustal and uppermost mantle depths include Hwang and Mitchell (1987) for several stable and tectonically active regions of the world, Al-Khatib and Mitchell (1991) for the western United States, and Cong and Mitchell (1998) for the Middle East.

Models have also been obtained in which Q_{μ} varies with frequency. That frequency dependence is described by the relation $Q_{\mu} = Q_0 f^{\zeta}$ where ζ may vary with frequency (Mitchell, 1975) and/or with depth (Mitchell and Xie, 1994). The inversion process for Q_{μ} in those cases requires appropriate extensions of the Anderson et al. (1965) equations. The process requires both fundamental-mode surface-wave attenuation data and Q or attenuation information for either an individual higher mode or the combination of higher modes that form the Lg phase. The process proceeds by assuming a simple one- or two-layer distribution of ζ and inverting the

fundamental-mode data for a Q_μ model. ζ is adjusted until a Q_μ model is obtained that explains both the fundamental-mode and higher-mode attenuation data. Mitchell and Xie (1994) applied the method to the Basin and Range Province of the western United States. Example Q_μ models for which ζ varies with depth (Mitchell and Xie, 1994) appear in **Figure 11**.

Other surface-wave studies for which the source is canceled are those that use many stations at various distances and azimuths and simultaneously solve for surface-wave attenuation coefficient values and seismic moments for particular periods by linear least squares. Tryggvason (1965) first did this, as described in our section on early studies, using explosions and assuming circular radiation patterns. Tsai and Aki (1969) extended this method to use earthquake sources and applied it to surface waves generated by the 28 June 1966 Parkfield, California, earthquake. This process was later applied to the central United States (Herrmann and Mitchell, 1975; Mitchell, 1973) and the Basin and Range Province of the western United States (Patton and Taylor, 1989).

A nonlinear variation of the Tsai and Aki method (Mitchell, 1975) represents a nuclear explosion with strain release by a superposition of an explosion (with a circular radiation pattern) and a vertical strike-slip fault (represented by a horizontal double couple). Variations of the orientation of the double couple and its strength relative to the explosion produce a wide variety of radiation patterns. The inversion solves for the moment of the explosion, the orientation of the double couple, the strength of the double couple relative to the explosion, and an average attenuation coefficient value for each period of interest. Mitchell applied the method to two nuclear events in Colorado as recorded by stations throughout the United States and found that Q_μ in the upper crust of the eastern United States is about twice as high as it is in the western United States at surface-wave frequencies.

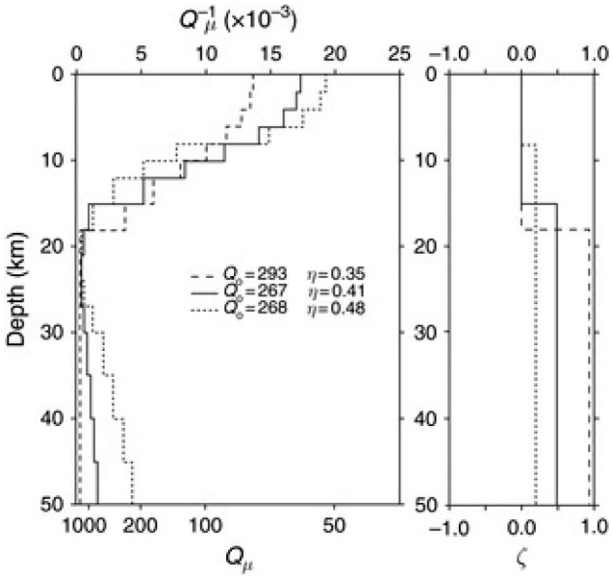

Figure 11 (Left) Three Q_μ models resulting from inversion of Rayleigh-wave attenuation coefficient data from the Basin and Range Province. The numbers refer to the value of Q_0 and η predicted by three models for Q_{Lg}. (Right) Three selected models for the variation of Q_μ frequency dependence with depth in the crust of the Basin and Range Province. Each of these depth distributions was fixed during inversions that produced Q_μ models. Reproduced from Mitchell BJ and Xie J (1994) Attenuation of multiphase surface waves in the Basin and Range province. Part III: Inversion for crustal anelasticity. *Geophysical Journal International* 116: 468–484, with permission from Blackwell Publishing.

The first attempts at mapping regional variations of attenuation or Q utilized crude regionalizations (two or three regions) based upon broad-scale geologic or geophysical information. Studies have produced models for Eurasia (Yacoub and Mitchell, 1977) using the method of Mitchell (1975) and for the Pacific (Canas and Mitchell, 1978) and Atlantic (Canas and Mitchell, 1981) using the two-station method.

1.25.7.2.3 Spectral decay methods in which source effects cancel: Lg coda

Lg coda, like direct Lg, is sensitive to properties through a known depth range (the crust) in which it travels and is a large amplitude phase for which data are plentiful. In addition, since the coda of Lg is comprised of scattered energy, it can continue to oscillate for several hundred seconds following the onset of the direct Lg phase, thus making it possible to stack spectral amplitudes for many pairs of time windows to make a Q estimate. Other positive aspects of using Lg coda for Q studies are that the averaging effect of scattering stabilizes Q_{Lg}^C determinations and, if stacking methods are utilized to determine Q for Lg coda, site effects cancel (Xie and Mitchell, 1990a).

Two methods have been applied to Lg coda to make Q determinations. The first of these was developed by Herrmann (1980) and applied by Singh and Herrmann (1983) to data in the United States. The method extended the coda theory of Aki (1969) utilizing the idea that coda dispersion is due to the combined effects of the instrument response and the Q filter of the Earth. The two studies provided new approximations for the relative variation of Q across the United States. Herrmann later realized, however, that his method did not take into consideration the broadband nature of the recorded signal and overestimates Q by about 30% (R. B. Herrmann, personal communication).

Xie and Nuttli (1988) introduced the stacked spectral ratio (SSR) method, which stacks spectra from several pairs of windows along the coda of Lg. That process leads to

$$R_k = f^{1-\eta}/Q_0 \qquad [16]$$

as the expression for the SSR, or in logarithmic form

$$\log R_k = (1-\eta)\log f_k - \log Q_0 + e \qquad [17]$$

from which Q_0 and η can be obtained by linear regression. f_k, Q_0, η, and e in these equations are, respectively, a discrete frequency, the value of Q at 1 Hz, the frequency dependence of Q at frequencies near 1 Hz, and an estimate for random error. This stacking process provides stable estimates of Q_0 and η with standard errors sufficiently low to allow tomographic mapping of those quantities. A detailed description of the SSR method appears in Xie and Nuttli (1988) and more briefly in Mitchell et al. (1997).

Figure 12 shows an example of Lg coda and its associated SSR for a relatively high-Q path in India, which can be fit over a

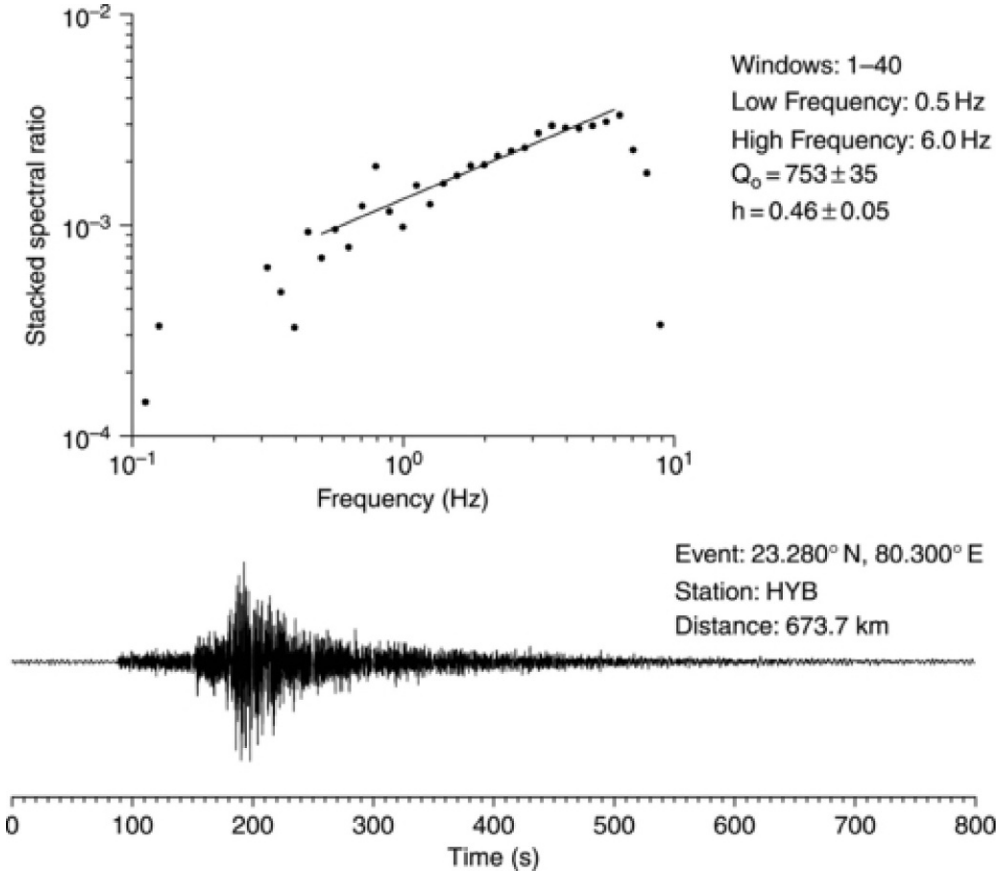

Figure 12 (Bottom) Seismogram. (Top) Stacked spectral ratio as a function of frequency for a relatively high-*Q* path in India.

broad frequency range with a straight line on a log–log plot. The value at 1 Hz provides an estimate of $1/Q$ at that frequency and the slope of the line gives an estimate for η. Inversions of sets of those values over a broad region can yield tomographic maps of those quantities.

Past studies have shown that several factors may contribute to reductions in Q_0; these include thick accumulations of young sediments (Mitchell and Hwang, 1987) and the presence of a velocity gradient rather than a sharp interface at the CMB (Bowman and Kennett, 1991; Mitchell et al., 1998). In addition, decreasing depth of the Moho in the direction of Lg travel or undulations of the Moho surface can be expected to decrease measured Q_{Lg} or Q_{Lg}^C, whereas increasing depth would produce larger values. To our knowledge, this effect has not been quantitatively studied and is expected to be small over large regions. These factors may cause determinations of correlation coefficients between Q_{Lg} or Q_{Lg}^C and various crustal or mantle properties to be relatively low whenever they are determined (e.g., Artemieva et al., 2004; Zhang and Lay, 1994).

1.25.7.2.4 Spectral decay methods for which assumptions are made, or information can be learned, about the source spectrum: regional phases

Hough et al. (1988) studied S waves traveling over relatively short distances near Anza, California, and defined the instrument-corrected acceleration spectrum at a station located a distance r from the source as

$$A(r,f) = A_0 e^{-\pi t^*} \quad [18]$$

where t^* is defined in eqn [12]. For crustal studies, it is common to assume that Q is constant along the path, in which case

$$t^* = \frac{t}{Q} \quad [19]$$

where t is the travel time.

Hough et al. (1988) defined A_0 as

$$A_0 = (2\pi f)^2 S(f) G(r,f) \quad [20]$$

where $S(f)$ is the source displacement spectrum and $G(r, f)$ is the geometric spreading factor, which, if we assume frequency-independent propagation in a homogeneous medium, is $1/r$ for body waves. At higher frequencies, these methods assume a spectral falloff rate (such as ω^{-2} or ω^{-3}) and attribute additional falloff to attenuation. Since a large body of data supports the ω^{-2}, or Brune, model (Brune, 1970), that is the one most commonly used. Taking the natural logarithm of eqn [18] leaves

$$\ln A(f) = \ln A_0 - \pi f t^* \quad [21]$$

For the frequency-independent case, this equation defines a straight line with an intercept of $\ln A_0$ and a slope of $-\pi t/Q_0$.

Anderson and Hough (1984) hypothesized that, to first order, the shape of the acceleration spectrum at high frequencies can be described by

$$\alpha(f) = A_0 e^{-\pi\kappa f} \quad f > f_E \qquad [22]$$

where f_E is the frequency above which the spectral shape is indistinguishable from spectral decay and A_0 depends on source properties and epicentral distance. They found that κ increased slowly with distance, an observation consistent with a Q model of the crust that increases with depth in its shallow layers and that it was systematically smaller on rock sites than at alluvial sites. Hough et al. (1988) studied κ as a function of hypocentral distance, as well as site and source characteristics, and found that $\kappa(0)$ differed for sites at Anza and the Imperial Valley in California but that $d\kappa/dr$ was similar for the two regions. Their interpretation was that $\kappa(0)$ was a component of attenuation that reflects Q_i in the shallow portion of the crust while $d\kappa/dr$ was due to regional structure at great depth. This method was applied to various regions in the world including the Canadian Shield (Hasegawa, 1974), the Pyrenees (Modiano and Hatzfeld, 1982), the New Madrid zone of the central United States (Al-Shukri et al., 1988), and eastern Asia (Phillips et al., 2000).

Shi et al. (1996) studied Q_{Lg} variation for five tectonically different regions of the northeastern United States. They used eight pairs of colocated earthquakes to determine accurate source spectrum corner frequencies by applying an empirical Green's function method to Pg and Lg or Sg phases. Based upon the corner frequencies, Sg or Lg displacement spectra were used to obtain values of Q and η values for 87 event–station paths at frequencies between 1 and 30 Hz. The 1 Hz Q_0 values for the five regions vary between 561 and 905 while η varies between 0.40 and 0.47.

1.25.7.2.5 Spectral decay methods for which assumptions are made about the source spectrum: fundamental-mode surface waves

A multimode spectral method has yielded simple crustal models (two or three layers) of shear-wave Q (Q_μ) in a few regions. The method assumes a flat source spectrum and tries to match theoretical amplitude spectra to two sets of observed spectral amplitude data, one corresponding to the fundamental mode and the other to the superposition of higher modes that forms the longer-period (3–10 s) component of the Lg phase. The higher modes travel faster than all but the longest-period fundamental-mode energy observed on records for relatively small events that are used with this method.

The first study using this method (Cheng and Mitchell, 1981) compared upper crustal Q_μ for three regions of North America and found values of 275 for the eastern United States, 160 for the Colorado Plateau, and 85 for the Basin and Range Province. Kijko and Mitchell (1983) applied the method to the Barents Shelf, a region of relatively high-Q crystalline crust overlain by low-Q sediments. They found the method to be sensitive to Q_μ in the sediments and upper crust but insensitive to Q_μ in the lower crust and to P-wave Q at all depths. Cong and Mitchell (1998) obtained models in which Q_μ is very low at all depths beneath the Iran/Turkish plateaus and somewhat higher but still much lower than expected beneath the Arabian Peninsula. Models they obtained using the multimode method agree well with those they obtained using the two-station method.

Jemberie and Mitchell (2004) applied the method to China and peripheral regions and obtained three-layer crustal models with low Q_μ and wide variation across China. Values decrease with depth beneath regions such as southeastern China and increase with depth beneath other regions such as the eastern Tibetan Plateau.

Seismologists have, in recent years, developed methods to measure the attenuation of regional phases (Pn, Pg, Sn, and Lg) in which the effects of source spectra are considered. One of those (Walter et al., 2007) used source spectra derived from the coda of those phases. It determined apparent Q by subtracting source spectra amplitudes from the observed amplitudes that were corrected for geometric spreading. They tested the method for several paths in Italy and found that they could determine path and recording site attenuation that satisfied the equation $Q(f) = Q_0 f^\eta$ well, for all phases, over the frequency range 0.5–8 Hz. Their measured values were also quite repeatable. Ford et al. (2008) compared several methods, including this one, for determining the attenuation of Lg in northern California. All methods returned similar values for Q_0 and η but with large 95% confidence regions ($Q_0 = 80 \pm 40$; $\eta = 0.65 \pm 0.35$). Another study of broadband Lg attenuation in the Middle East (Pasyanos et al., 2009) used the magnitude and distance amplitude correction developed by Walter and Taylor (2001). The method formulates the source term in terms of a corner frequency ω_c with an ω^{-2} falloff (Aki, 1967 and others) where the corner frequency and source term include constants that depend on medium properties as well as seismic moment. Their studies compared favorably with the results found by other studies in the region and, like those studies, showed a strong correlation with tectonics.

1.25.7.3 Tomographic Mapping of Crustal *Q*

Seismologists are currently attempting to map variations of Q and its frequency variation in the Earth in as much detail as possible. For continents, researchers have obtained tomographic maps for several broad regions using Lg coda, the direct Lg phase, and surface waves. Studies using P and S waves have yielded important results in regions where earthquakes and recording stations are plentiful. Studies of even smaller regions, such as volcanoes and geothermal areas, have utilized P and S waves (e.g., Hough et al., 1999). In this chapter, we restrict our discussion to more broad-scale studies.

An earlier section described three early regionalized studies of surface-wave attenuation in the late 1970s and early 1980s, one for continental paths and two for oceanic paths in which the Eurasian continent, the Pacific Ocean, and Atlantic Ocean were divided into two or three regions. Since then, tomographic mapping using Lg coda has made possible a much finer regionalization of crustal Q in continents. This section will discuss tomography results for continents and for one oceanic region using either direct Lg, fundamental-mode surface waves, or P and S waves.

We emphasize Lg coda since tomographic maps of Q_{Lg}^C, all obtained for the same frequency and using the same methodology, are available for all continents except Antarctica. This

commonality in phase, frequency, and method allows us to compare Q from one continent to that in others and also to various geophysical and geologic properties. These comparisons contribute to our understanding of the mechanisms for seismic-wave attenuation in the crust.

Earlier sections have indicated that Lg coda has several properties that make it useful for tomographic studies. First, it is usually a large amplitude phase making it easily available for study in most regions of the world. Second, it is a scattered wave and the averaging effect of that scattering makes Lg coda relatively insensitive to focusing. Third, the SSR method used to determine Q_0 and η tends to cancel site effects. Fourth, although it is a scattered wave, measurements of Q for seismic coda have been shown theoretically and computationally to yield measures of intrinsic Q (e.g., Frankel and Wennerberg, 1987; Mitchell, 1995; Sarker and Abers, 1999). If that is correct, researchers can interpret Q variation in terms of Earth structure and evolution. Other studies, however (e.g., Aki, 1980; Gusev and Abubakirov, 1996) attribute energy loss to scattering.

Akinci et al. (1995), employing the energy partition method of Frankel and Wennerberg (1987) for a Q study in western Turkey, found that shear-wave scattering predominated at low frequencies (1–4 Hz) and short hypocentral distances (0–80 km). Intrinsic anelasticity, however, became the dominant contributor to attenuation at greater distances. Cicerone et al. (2011) obtained a similar result for northeastern North America, while Sahin et al. (2013) also came to that conclusion when studying Lg attenuation in central Turkey. Those three studies suggest that for typical studies of Lg attenuation at large distances (about 200 km and more), Q values will largely reflect intrinsic properties of the Earth's crust.

Mitchell et al. (2014) proposed that the reason these path length-dependent differences occur can be understood by considering a supposition of rays taken to characterize Lg propagation. At very short lateral distances, most of the rays that comprise shear waves are reflected at angles smaller that the critical angle. For that reason, much of the wave energy at short distances is scattered into the mantle and quickly lost. At large lateral distances, waves that combine to form Lg reflect off the crust–mantle boundary (and other crustal boundaries) at angles that exceed the critical angle. That being the case, Lg and its coda will be largely constrained to travel in the crust, and relatively little energy is lost to the mantle.

As indicated earlier, Lg coda Q (Q_{Lg}^{C}) is typically assumed to follow a power-law frequency dependence, $Q_{Lg}^{C} = Q_0 f^{\eta}$, where Q_0 is the Q value at 1 Hz and η is the frequency dependence of Q near 1 Hz. Tomographic maps of the 1 Hz values of Q_{Lg}^{C} (Q_0 and η) with nearly continent-wide coverage are now available for Eurasia (Mitchell et al., 1997, 2008), Africa (Xie and Mitchell, 1990b), South America (DeSouza and Mitchell, 1998), and Australia (Mitchell et al., 1998). In North America, broad-scale determinations of Q_{Lg}^{C} are currently restricted to the United States (Baqer and Mitchell, 1998). These studies have shown a wide range of average Q_0 values for different continents and a very wide range within each continent. Average Q_0 tend to be highest in continents that contain the most old stable cratonic regions that have not undergone later tectonic or orogenic activity (e.g., Africa and South America).

Tomographic studies have also been completed for more restricted regions using the direct Lg phase in Eurasia, North America, and South America, and high-resolution tomographic maps of Q for P and S waves are available for southern California. For oceanic regions, tomographic mapping of Q variations, to our knowledge, is currently available only for P waves in one broad portion of the East Pacific Rise (Wilcock et al., 1995).

Sarker and Abers (1998) showed that, for comparative studies, it is important that researchers use the same phase and methodology in comparative Q studies. The Lg coda Q maps presented here adhere to that principle; thus, the continental-scale maps of Q_0 and η for Lg coda at 1 Hz that are available can be considered to provide the closest thing to global Q coverage at crustal depth that currently exists. The maps also present the possibility for comparisons of Q_0 variation patterns with variations in seismic velocity, temperature, plate subduction, seismicity, the surface velocity field, and tectonics when that information is available.

A discussion of the inversion method for mapping Q_0 and η appears, in detail, in Xie and Mitchell (1990b) and, more briefly, in Mitchell et al. (1997). The method assumes that the area occupied by the scattered energy of recorded Lg coda can be approximated by an ellipse with the source at one focus and the recording station at the other, as was shown theoretically by Malin (1978) to be the case for single scattering.

Xie and Mitchell (1990b) utilized a back-projection algorithm (Humphreys and Clayton, 1988) to develop a methodology for deriving tomographic images of Q_0 and η over broad regions using a number of Q_0 or η values determined from observed ground motion. **Figures 13–17(a)** show the ellipses that approximate data coverage for the event–station pairs used in Q_{Lg}^{C} studies of Eurasia, Africa, South America, Australia, and the United States. The inversion process assumes that each ellipse approximates the spatial coverage of scattered energy comprising late Lg coda. The areas of the ellipses grow larger with increasing lag time of the Lg coda components. The ellipses in the figure are plotted for maximum lag times used in the determination of Q_0 and η. Ideally, each inversion should utilize many ellipses that are oriented in various directions and exhibit considerable overlap in order to obtain the redundancy needed to obtain the best possible resolution for features of interest. Xie and Mitchell (1990b) discuss the procedure in detail, presenting methods for obtaining standard errors for Q_0 and η and for estimating spatial resolution.

Because Lg coda consists of scattered energy, it must be distributed, for each event–station pair, over an area surrounding the great-circle path between the source and receiver. Because of this areal coverage, our maps may not include effects of Lg blockage in regions where such blockage has been reported. We may have no data from blocked paths but are likely to have other paths, such as those subparallel to the blocking feature or for which the source or recording station, represented by one focus of the scattering ellipse, lies near the blocking feature. In both cases, portions of the scattering ellipses may overlap the blocking feature, but that feature will not substantially contribute to the values we obtain for Q_0 and η. A comparison of mapped Q_0 for all continents (**Figures 13–17(b)**) shows that it is typically highest in the stable portions of the continents and lowest in regions that are, or recently have been, tectonically active. Exceptions occur, however, especially for stable regions. For instance, the Arabian

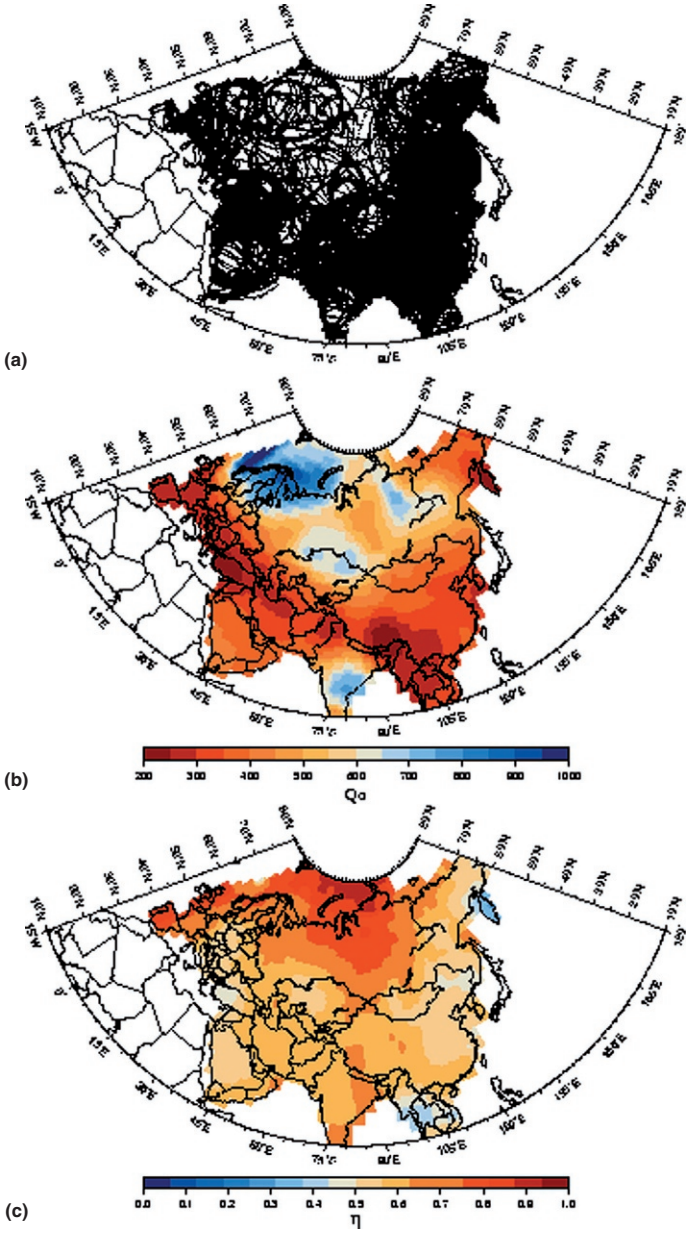

Figure 13 (a) A scattering ellipse map, (b) a Q_0 map, and (c) an η map for Eurasia. Adapted from Mitchell BJ, Cong L, and Ekström G. (2008) A continent-wide 1-Hz map of *Lg* coda *Q* variation across Eurasia and its implications for lithospheric evolution. *Journal of Geophysical Research* 113. http://dx.doi.org/10.1029/2007JB005065.

Peninsula, although being a stable platform, shows Q_0 variations between 300 and 450, values that are one-half or less of maximum values in other Eurasian platforms. Other regions showing lower than expected Q_0 include the Siberian Trap region of northern Siberia and the cratonic regions of Australia.

The frequency dependence values of $Q_{\mathrm{Lg}}^{\mathrm{C}}$ (η) in Figures 13–17(c) appear to show consistent relationships to Q_0 in some individual continents. For instance, in both Africa and South America, high-*Q* regions are typically regions of low η. That same relationship, however, does not occur consistently in Eurasia, Australia, or the United States. η is high, for instance, throughout much of the northern portions of Eurasia where Q_0 is mostly high but is low in California, Kamchatka, and a portion of southeast Asia where Q_0 is very low.

1.25.7.3.1 Q_{Lg}^{C}, Q_{Lg}, and Q_{μ} tomography in regions of Eurasia

Figure 13 shows maps of data coverage, Q_0, and η across most of Eurasia (Mitchell et al., 2008). These maps represent a major increase in data coverage for northeastern Siberia, southeastern Asia, India, and Spain, compared to those of an earlier study (Mitchell et al., 1997) and provide additional redundancy in regions where there was earlier coverage. As indicated in Figure 13(a), the data coverage is excellent for virtually all of

Eurasia. Low Q_0 values extend through the Tethysides belt that extends across southern Eurasia from western Europe to eastern China, and its southern portions appear to be related to subduction processes occurring at the present time. Q_0 is generally high in the platforms of northern Eurasia and India (600–950). It is, however, low in the Kamchatka Peninsula and regions directly north of there, which, like the Tethysides region, are seismically active. A conspicuous region of relatively low Q_0 lies in central Siberia and corresponds spatially to the Siberian Traps.

The four zones with lowest Q values lie in the Kamchatka Peninsula in northeastern Siberia, the southeastern portions of the Tibetan Plateau and Himalaya, and the Hindu Kush (just north of India) and western Turkey. All of these regions are also highly seismically active, a correspondence that suggests that low-Q regions are associated with regions of high crustal strain.

Other low-Q regions appear to be related to upper mantle processes. A comparison of **Figure 13(b)** with wave velocities at long periods (Ekström et al., 1997), which are not sensitive to crustal properties, shows a correspondence of low-Q regions with regions of low upper mantle velocities. This is most apparent for the broadband of low Q values throughout southern Eurasia but also occurs in the Siberian Trap region of Siberia. Both the low-Q and low-velocity regions largely coincide with high upper mantle temperatures (Artemieva and Mooney, 2001).

Patterns of frequency dependence (η) variation in **Figure 13(c)**, in contrast to those of Q_0 variation, show no clear-cut relationship to tectonics. They similarly show no relation to patterns of Q_0 variation. For instance, Kamchatka has low Q_0 and low η while Spain has low Q_0 and high η.

Seismologists have performed other tomographic studies for portions of Eurasia using Q_{Lg} and shear-wave Q (Q_μ). Xie et al. (2006) used a two-station version of the SSR method to determine more than 5000 spectral ratios over 594 paths in eastern Eurasia. They were able to obtain tomographic models for Q_0 and η with resolution ranging between 4° and 10° in which Q_0 varies between 100 and 900.

Using the single-station multimode method, Cheng and Mitchell (1981) and Jemberie and Mitchell (2004) obtained tomographic maps of shear-wave Q (Q_μ) for depth ranges of 0–10 and 10–30 km. Although large standard errors accompany those determinations, several features of their variation patterns, such as the low-Q regions in southern Tibet, resemble the map of Q_0 variations (**Figure 13(b)**). Q_μ varies between about 30 and 280 in the upper 10 km of the crust and between about 30 and 180 at 10–30 km depth.

1.25.7.3.2 Q^C_{Lg} tomography in Africa

Xie and Mitchell (1990b), in the first tomographic study of Lg coda, determined Q_0 and η for continental Africa. **Figure 14** shows maps of data coverage, Q_0 and η for that entire continent (Xie and Mitchell, 1990b). The feature in the Q_0 map (**Figure 14(b)**) that is most obviously related to tectonics is the low-Q region that broadly coincides with the East African Rift system. The three high-Q regions correspond to Precambrian cratons: the West African Craton in the northwest, the East Sahara Craton in the northeast, and the Kalahari Craton in the south. The Congo Craton, situated just to the north of the Kalahari Craton does not show up as a region of high Q, probably because waves are damped by a broad and deep basin of low-Q sedimentary rock in that region.

Low Q_0 values also occur in the Atlas Mountains (Cenozoic age) of northern Africa, the Cape Fold Belt (Permian–Triassic age) at the southern tip of Africa, and the Cameroon line (Miocene age), which is oriented in an NNE–SSW direction from the point where the western coast changes direction from east–west to north–south.

1.25.7.3.3 Q^C_{Lg} and Q_{Lg} tomography in South America

Figure 15 shows data coverage and values of Q_0 and η obtained for South America (DeSouza and Mitchell, 1998). The data coverage (**Figure 15(a)**) is excellent throughout western South America where seismicity is high but poor in eastern regions, especially the most easterly regions, where there are few earthquakes. **Figure 15(b)** shows that, as expected, the low-Q (250–450) portion of South America is associated with the tectonically active western coastal regions. The lowest Q_0 values occur along the coast between 15° and 25° S latitude where the level of intermediate-depth seismicity is highest in the continent. The slab in this region also dips steeply (>20°) and significant volcanism occurs (Chen et al., 2001). Davies (1999) had studied the role of hydraulic fractures and intermediate-depth earthquakes in generating subduction zone magmatism. He suggested that the level of intermediate-depth earthquakes was high because liberated fluids favored brittle fracture in response to stresses acting on the slab. Q levels may be low there because earthquake activity creates a degree of permeability that allows dehydrated fluids to be transported to the mantle wedge.

Ojeda and Ottemöller (2002) developed maps of Lg attenuation for most of Colombia at various frequencies in the 0.5–5.0 Hz range. They delineated regional variations of Q_{Lg} within that relatively small region.

1.25.7.3.4 Q^C_{Lg} tomography in Australia

Figure 16 shows the data coverage and values of Q_0 and η obtained for Australia (Mitchell et al., 1998). Data coverage (**Figure 16(a)**) there was the poorest of the five continents where $Q^{\mathrm{C}}_{\mathrm{Lg}}$ was mapped over continent-scale dimensions. Q_0 variation there is consistent, however, with the other studies, and, for all but peripheral regions where systematic measurement errors can be high, it displays a clear relationship with past tectonic activity. Q_0 in Australia (**Figure 16(b)**) is unusually low for a stable continental region, perhaps because a velocity gradient rather than a sharp interface separates the crust and mantle.

Highest values range between 550 and 600 in the southeastern corner of the continent (the Yilgarn Block) and along the southern coast (the Gawler Block). Values between 400 and 500 characterize much of the remaining cratonic crust. This compares with values of 800 and higher in most of the African and South American cratons. The youngest crust lies in eastern Australia where Q_0 is between 350 and 400. An orogeny occurred there during the Devonian Period, and another occurred in the eastern portion of that region during the Permian Period. Low Q_0 values in the most westerly point of the continent and along the northern coast are probably due to very poor data coverage there (**Figure 16(a)**) and are probably meaningless.

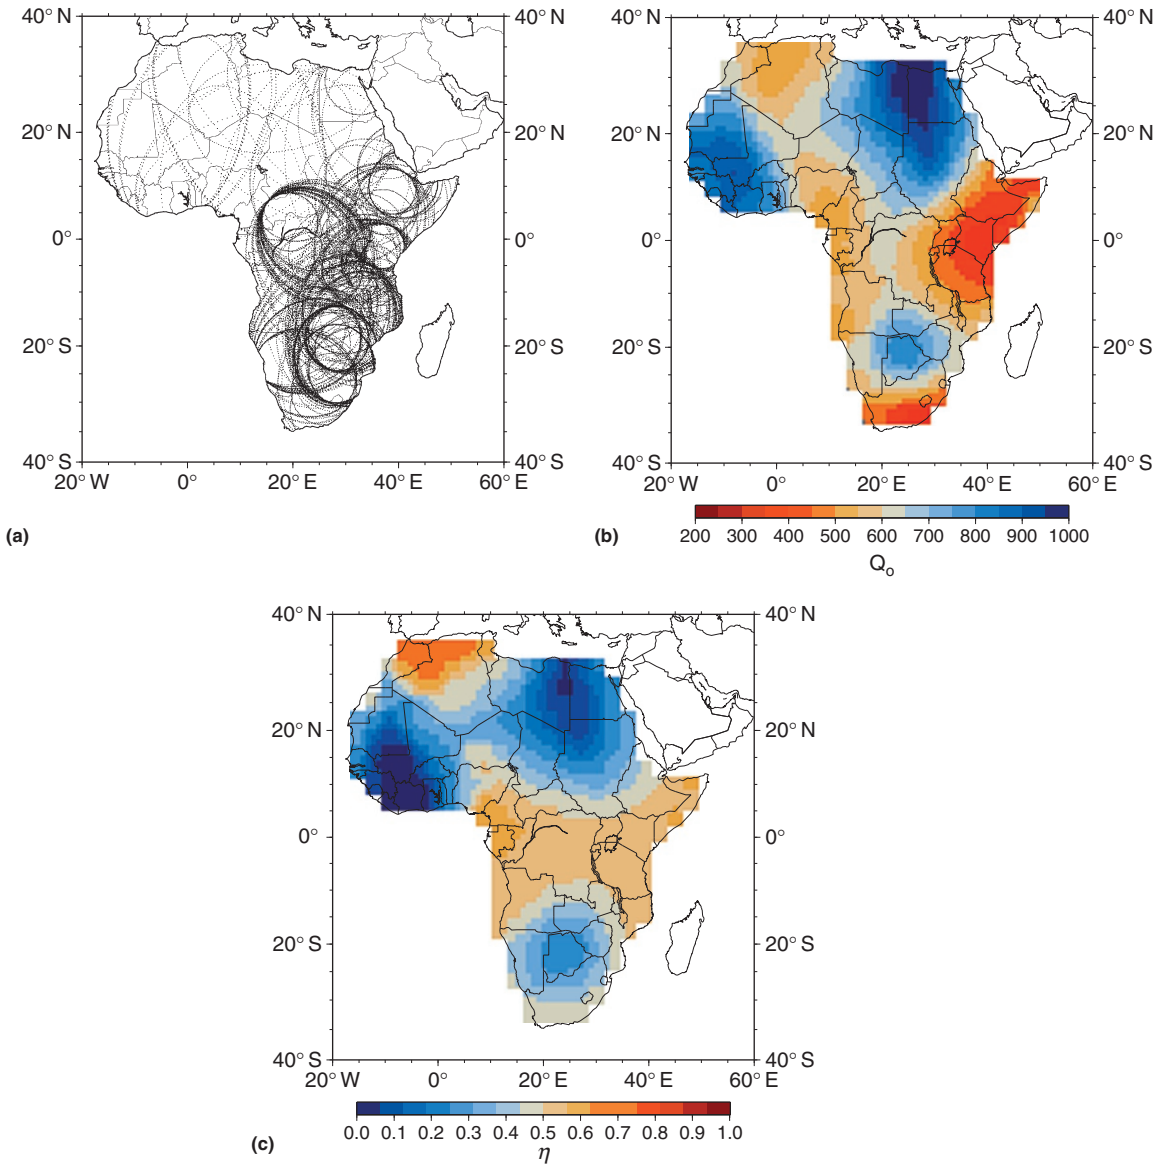

Figure 14 (a) A scattering ellipse map, (b) a Q_0 map, and (c) an η map for Africa. Adapted from Xie J and Mitchell BJ (1990b) A back-projection method for imaging large-scale lateral variations of *Lg* coda *Q* with application to continental Africa. *Geophysical Journal International* 100: 161–181.

1.25.7.3.5 Q^c_{Lg}, Q_{Lg}, and P/S tomography in North America

Figure 17(a) shows approximate data coverage and values of Q_0 and η for the first Lg coda *Q* study of the entire North American continent (Mitchell et al., 2014). This work utilized 1122 event–station pairs distributed across virtually all of North America, a number that represents a more than fivefold increase in data coverage over that of an earlier Lg coda *Q* study of the United States (Baqer and Mitchell, 1998). Data coverage is densest in the westernmost portion of North America where seismicity rates are high but coverage is also more than adequate for most of the rest of the continent. This is especially true for the south-central and northeastern portions of the United States, as well as for southeastern Canada. The ability to use relatively small earthquakes, even in central and north-central Canada where seismicity rates are low, allowed us to achieve quite good data coverage.

The Q_0 map (Figure 17(b)) reveals two major features that cover vast areas of North America. One is a region of high-*Q* values (700–1000) that covers much of the Canadian Shield with a southeastern arm that extends through southern New England and New York to the Atlantic coast. The other is a band of low-*Q* values (about 200–350) that runs continuously, with some variations in width (between about 20 and 500 km), from southern Alaska to southern Central America. The transition from the high-*Q* shield values to low values in western Canada is surprisingly sharp and suggests that the pattern of mapped Q_0 cannot be explained as being produced by temperature variations alone in the crust. One possibility that would nicely explain the sharp transition is a change from high levels of interstitial fluid content in the low-*Q* region compared to lower fluid levels in the high-*Q* region.

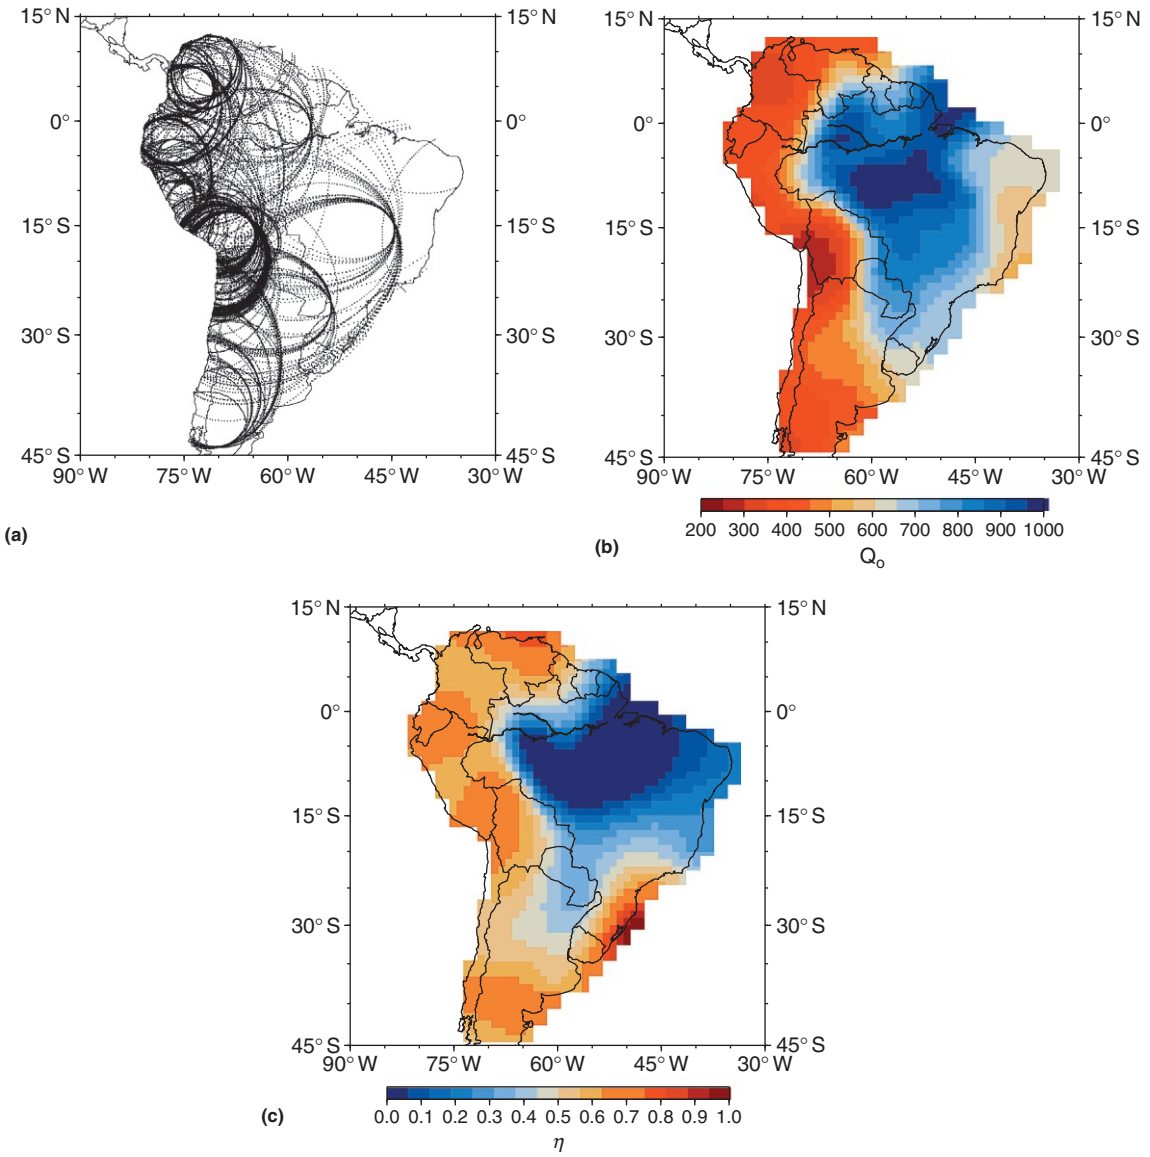

Figure 15 (a) A scattering ellipse map, (b) a Q_0 map, and (c) an η map for South America. Adapted from DeSouza JL and Mitchell BJ (1998) *Lg* coda *Q* variations across South America and their relation to crustal evolution. *Pure and Applied Geophysics* 153: 587–612.

A small but important feature on the map appears as a circular region of high Q_0 values (600–700) with a diameter of about 500–700 km in the central United States. It coincides well with the Ozark uplift of southern Missouri and northern Arkansas. The region of relatively high Q_0 includes the St. Francis Mountains, a region of Precambrian rock, which contains some of the oldest rock in North America.

One region of moderately low Q_0 values includes the east–west band that extends from the eastern edge of very low-Q_0 regions of southern California and northern Mexico through southern portions of the Gulf coast states and northward along the Atlantic coast to an extension of the high-Q_0 Canadian Shield. Another is the relatively low-Q_0 band from northeastern Canada through most of the continental shelf of northern Canada. All of these features are probably due to the accumulations of thick sediments known to occupy those regions.

Figure 17(c) shows the distribution of the frequency dependence parameter (η) for North America. The excellent coverage of this study makes possible a better understanding of the regional variation in η than has been previously possible. The most striking feature of the map is the high-η band stretching from northern Canada to the western coast of the Gulf of Mexico. The highest values stretch northward from Great Slave Lake to the coast and are associated with high errors for both Q_0 and η. This probably indicates that crustal complexity, not intrinsic rock properties, causes anomalous values for η. More moderate η values (0.6–0.8) extend southward from the Great Slave Lake anomaly to the Gulf of Mexico. Lower values (0.3–0.6) characterize four regions of North America: (1) the Canadian Shield, (2) the eastern United States, (3) the western United States, and (4) the region of northwestern Canada and southern Alaska. We have discussed the likelihood that the very

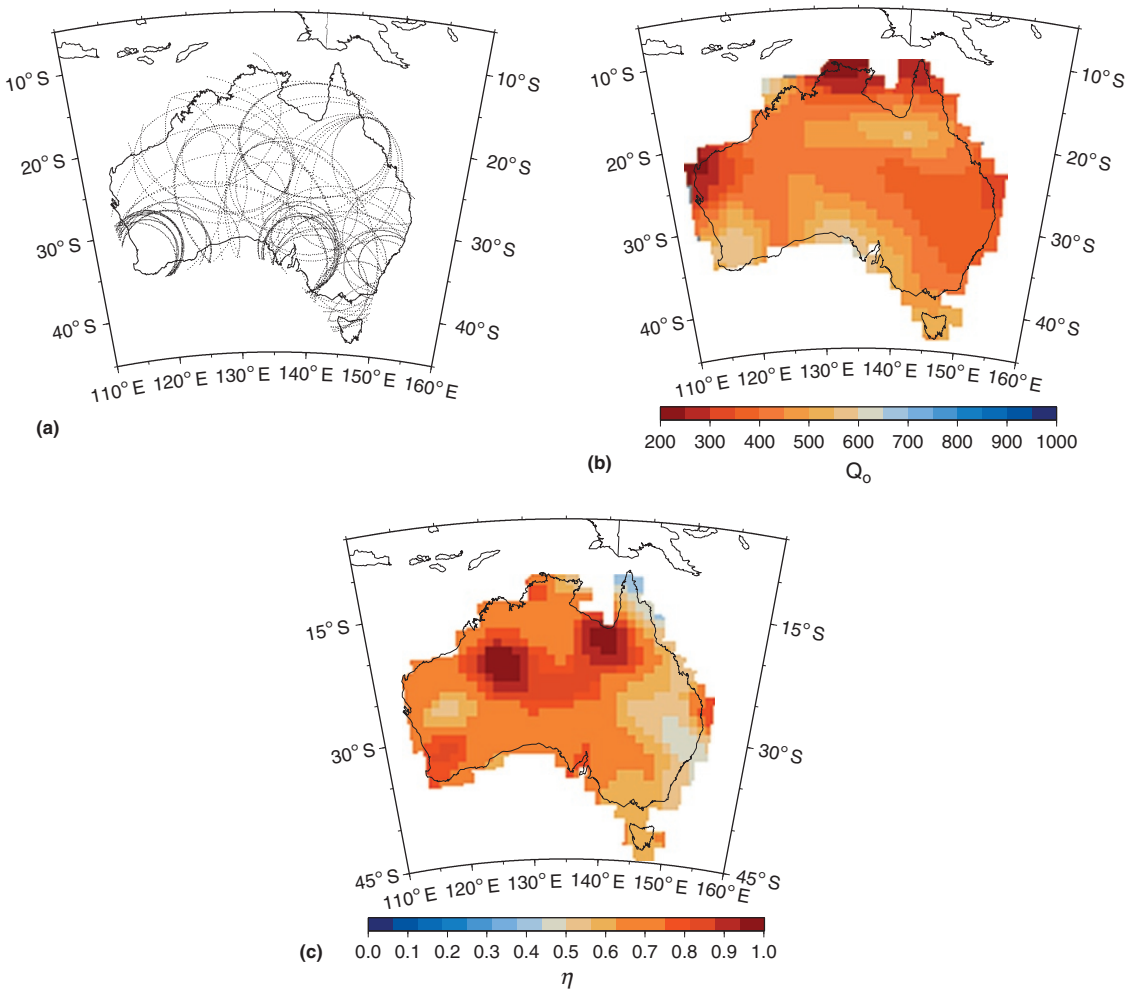

Figure 16 (a) A scattering ellipse map, (b) a Q_0 map, and (c) an η map of Q_{Lg}^{C} for Australia. Adapted from Mitchell BJ, Baqer S, Akinci A, and Cong L (1998) *Lg* coda *Q* in Australia and its relation to crustal structure and evolution. *Pure and Applied Geophysics* 153: 639–653.

high η values (0.8–1.0) in northern Canada are due to scattering causing the crustal complexity known to exist there. A broadband of high η values (0.6–0.8) extends southward from the concentration of highest values forming a long and broad high-η band extending from there to the Gulf of Mexico. That band lies between the Great Plains on its eastern side and the Rocky Mountains on its western side and may be caused by a transition zone with changing east–west crustal thickness.

Two research groups have studied the 3D structure of P-wave and S-wave attenuation in southern California. Schlotterbeck and Abers (2001) fit theoretical spectra to observed spectra using the least-square minimization method of Hough et al. (1988) and determined t^* for P and S waves at frequencies between 0.5 and 25 Hz. Their inversions showed that P and S results were in substantial agreement, and that Q varies spatially and correlates with regional tectonics.

The second California study (Hauksson, 2006) also determined t^* from P- and S-wave spectra. They assumed that t^* consists of the sum of the whole-path attenuation and the local site effect at each recording station and utilized an expression of Eberhart-Phillips and Chadwick (2002) for the velocity spectrum. The inversion, in addition to providing t^*, yields parameters defining the velocity amplitude spectra. They determined t^* for about 340 000 seismograms from more than 5000 events of t^* data to obtain 3D, frequency-independent crustal models for Q_P and Q_S in the crust and uppermost mantle in southern California. They found that both Q_P and Q_S generally increase with depth from values of 50 or less in surface sediments to 1000 and greater at midcrustal depths. Their models reflect major tectonic structures to a much greater extent than they reflect the thermal structure of the crust. Al-Eqabi and Wysession (2006) conducted a tomographic study of Q_{Lg} in the Basin and Range Province using a genetic algorithm technique. They found that Q_{Lg} increases (234–312) in a southwest–northeast direction across the Basin and Range Province in good agreement with the variation of Q_{Lg}^{C} reported by Baqer and Mitchell (1998). As part of a broader study of Lg wave propagation in southern Mexico, Ottemöller et al. (2002) used formal inversion methods to separately obtain tomographic maps of Q_{Lg} at three frequencies (0.5, 2.0, and 5.0 Hz) using 1° by 1° cells. Because of uneven path coverage in southern Mexico, they applied regularization conditions to their inversion equations. They found lower than average Q_{Lg} in the Gulf of Mexico coastal plain and the area east of 94° W,

average values in the northern portion of the Pacific coastal region, and below average values in the southern portion.

1.25.7.3.6 Q_P variation near ocean ridges

Wilcock et al. (1995) developed a spectral technique by which they determined the attenuation of P waves in an active-source experiment centered at the East Pacific Rise at latitude 9°30′N. It is, to date, the only tomographic study of crustal Q variation in an oceanic region. They obtained over 3500 estimates of t^*, the path integral of the product of Q^{-1} and P-wave velocity where both quantities are variable along the path. Wilcock et al. display plots of both cross-axis and along-axis structures for upper crustal and lower crustal Q^{-1} structures. Within the ridge magma chamber, Q reaches minimum values of 20–50, which extend to the base of the crust. Off the ridge axis, they find that Q in the upper crust is 35–50 and at least 500–1000 at depths greater than 2–3 km.

1.25.7.3.7 Variation of crustal Q with time

Several investigators (e.g., Chouet, 1979; Jin and Aki, 1986) have reported temporal variations of Q over timescales of a few years. Although this observation has been reported several times, it continues to be controversial. Spatial patterns of Q variation and their apparent relation to time that has elapsed since the most recent episode of tectonic activity in any region, however, suggest that temporal variations of Q over very long periods of time can easily be detected. Mitchell and Cong (1998) found that variation for Q_{Lg}^{C} at 1 Hz extends between roughly 250, for broad regions that are currently tectonically active, and about 1000 for shields that have been devoid of tectonic activity for a billion years or more (Figure 18). Mitchell et al. (1997) explained those observations as being due to variable volumes of fluids in faulted, fractured, and permeable rock. Fluids may enhance the rate of attenuation of seismic waves either because the waves must expend energy to push those fluids through permeable rock as they propagate or because they may traverse a region of enhanced scattering that causes loss of wave energy into the mantle. Figure 18 points to an evolutionary process in which fluids are relatively abundant in tectonically active regions due to their generation by hydrothermal reactions at high temperatures. With time, fluids are gradually lost, either by migration to the Earth's surface or absorption due to retrograde metamorphism. This process causes low Q values early in the tectonic cycle and gradually increasing values at later times as the fluids dissipate.

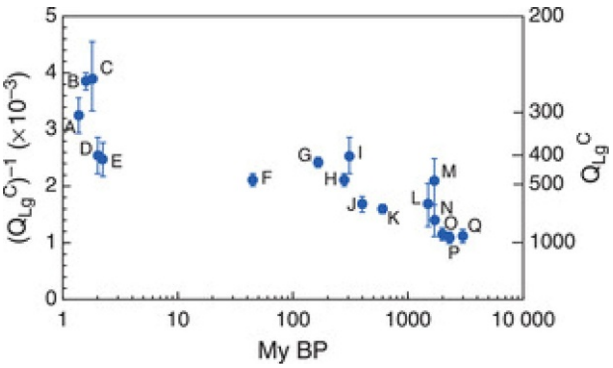

Figure 18 Q_0 for Q_{Lg}^{C} at 1 Hz versus time elapsed in selected regions since the most recent episode of tectonic or orogenic activity. 1.25.8 Conclusions

Much progress has been made in the last 15 years in characterizing the lateral variations in attenuation in the crust, especially under continents, and their relation to tectonics. Characterizing the nature and distribution of attenuation deeper in the Earth still remains a challenging subject, because of the persistent difficulties in separating anelastic and scattering effects and the nonuniform sampling achieved with available data.

Still, it is encouraging to see that there is now consistency in the large-scale features of lateral variations in Q in the upper 200 km of the mantle, correlated with tectonics, and that accounting for focusing effects using a single scattering approximation in present-day elastic 3D models is helpful, at least at the longest wavelengths. It is still important to consider that, when the inversion experiment is well designed, the unmodeled scattering effects can be minimized, or even utilized to constrain velocity models (e.g., Dalton and Ekström, 2006b), but the consequence is that significant damping needs to be applied in the inversion for lateral variations in Q. This results in large uncertainties (a factor of 2 or more) in the amplitudes of lateral variations of Q, so that physical interpretations of these models must remain tentative. On the other hand, the spatial distribution of low- and high-Q regions is, in general, more robust. Thus far, only one research group has produced models of lateral variations of Q_μ in the transition zone. While the results are consistent within this group using different methodologies (Gung and Romanowicz, 2004; Romanowicz, 1995) and point to an intriguing correlation with structure at the base of the mantle (Romanowicz and Gung, 2002), these results need to be confirmed by independent studies.

At the regional, uppermost mantle scale, consistent results have been obtained in subduction zones (high Qs) and back-arc regions (very low Qs), less so in oceanic settings. A promising trend, made possible by improved data and techniques, is to combine attenuation, velocity, and other geophysical parameters to better constrain lateral variations of temperature and composition. An ambitious goal would be to do the same at the global, and deeper, scale. Progress in laboratory experiments on Q at seismic frequencies is just starting to provide reliable mineral physics parameters on the behavior of Q at depths down to the upper mantle low-velocity zone, so that joint inversions of seismic waveform data for elastic and anelastic 3D structure can be envisaged (e.g., Cammarano and Romanowicz, 2007, 2008). The challenge

here is in the nonlinearities introduced by the exponential variation of Q with temperature, on the one hand, and the variation in the position of mineral phase changes depending on composition, on the other.

Important uncertainties remain in the characterization of the 1D profile of Q_μ in the mantle – first and foremost, explaining once and for all the discrepancy between free oscillations and surface-wave measurements, which has consequences for the value of Q_μ in the transition zone. Because there are still unexplained discrepancies between elastic models of the upper mantle, and particularly the transition zone, produced from seismic data, on the one hand, and from mineral physics data and computations, on the other (e.g., Cammarano et al., 2003), it is particularly important to apply accurate anelastic corrections when interpreting seismic velocity models in terms of composition. The evidence for a maximum in Q_μ in the lower mantle, and therefore lower Q_μ at the base of the mantle, is now clear; however, the location of this maximum is not well constrained. The confirmation of frequency dependence of Q in the mantle, with $\alpha \sim 0.3$, and a shift of the absorption band to lower frequencies in the lower mantle, seems to emerge from the comparison of 1D Q profiles derived from normal modes/surface-wave data, on the one hand, and body-wave data, on the other. The location in the Earth of the attenuation in bulk required to explain some normal mode data is still the subject of debate.

The presence of hemispheric variations in Q_α at the top of the inner core and the confirmation of increasing Q with depth and of anisotropy in Q_α correlated with anisotropy in velocity are exciting results that need further investigation, in particular in the light of recent studies by Li and Cormier (2002) favoring a scattering interpretation of attenuation in the inner core.

Finally, in the shallow Earth, it has been found over the past four decades that crustal Q, as manifested by regional studies of body waves, Lg and Lg coda, varies tremendously across continents, as well as in average values of different continents. Q_0 for Lg coda varies between about 150 and 1000 for features that can be resolved at 1 Hz frequency and the frequency dependence of Lg coda Q varies between about 0.0 and 1.0. Recent work on energy partitioning to learn the extent to which Lg attenuation is governed by intrinsic rock properties or by scattering shows that while scattering is predominant at short distances, intrinsic rock properties play the larger role at long distances. Most Q determinations at short periods in any region appear to be governed, most prominently, by the time that has elapsed since the most recent episode of tectonic or orogenic activity there.

Further advances in mapping the Q structure in the crust and mantle may come from the implementation of novel methodologies, such as the use of powerful numerical techniques for wavefield computations (e.g., Ruan and Zhou, 2012; Savage et al., 2010) and the use of noise correlation data (e.g., Lawrence and Prieto, 2011; Prieto et al., 2009; **Chapter 1.12**).

1.26.1 Introduction

Earth is unique among the planets as the only body for which we have a detailed picture of its internal structure. We may compare that part of seismology concerned with Earth structure to an experimental science concerned with a single, very large sample. The source of illumination is generated naturally, mainly in the form of earthquakes, many each year large enough to generate measurable ground accelerations at the antipodes. (There are typically more than ten major, magnitude 7–8; 100 large, magnitude 6–7; and 1000 damaging, magnitude 5–6 earthquakes each year. Prior to the current international moratorium, nuclear explosions have also provided seismic illumination of the Earth's deep interior: magnitudes of 5, 6, and 7 correspond roughly to yields of 32 kt, 1 Mt, and 32 Mt. In addition, storms, volcanic eruptions, bolide impact, and other phenomena create an ambient background field of 'seismic daylight.') The detectors are seismic recording stations, which now number in the hundreds of high quality (e.g., producing broadband, three-component digital records). The basic measurement is of the travel time from source to receiver, from which can be deduced the elastic-wave velocity along the path of propagation; the displacement versus time (waveform) shown by the seismic record also provides information about the spatial gradients of wave velocity at depth. Millions of crossing rays have illuminated every corner of the interior, leading to models of Earth structure in which the velocity is considered known to within 1%. In addition, the frequencies of the Earth's resonances (free oscillations or normal modes) excited by large earthquakes, typically determined to a part in 10^3 for hundreds of overtones, provide important information on the distribution of density at depth.

Such extraordinary precision rivals or exceeds our ability to measure elastic-wave velocities in the laboratory at conditions representative of most of the Earth's interior. In reality, the seismological determination of velocity is somewhat more limited than this comparison would suggest, primarily by spatial resolution: the smaller the region of interest, the larger the uncertainties (Gilbert et al., 1973).

Earth is unusual as an experimental sample in ways other than its large size. Pressure, temperature, and composition are all inhomogeneous, and the spatial variations of these quantities are due to processes internal to the planet, rather than being externally imposed. Temperature and compositional fields both show large radial and lateral variations that are the product of the Earth's origin, evolution, and dynamics. But how to determine these quantities? We have no *in situ* measurements of either temperature or composition below the crust, and seismology alone does not suffice: only the elastic-wave velocities and density are measured, not temperature or composition.

A central concern of mineral physics has been to uncover the nature of the Earth's internal temperature and composition, with a view toward placing critical observational constraints on the planet's history and geologic processes. For example, by recognizing the connection between the bulk-sound velocity determined seismologically and the compressibility ($1/K_S$), Williamson and Adams (1923) showed that much of Earth structure can be explained by adiabatic

self-compression of matter with depth. By comparing seismological models and experimental – mostly shock wave – data, Birch identified iron as the primary constituent of the Earth's core and the mean atomic mass of the mantle as being similar to that of certain xenoliths (rock fragments of the Earth's interior brought to the surface by volcanic processes) (Birch, 1952). Ringwood, Akimoto, and others showed that seismologically observed mantle discontinuities can be explained by phase transformations observed in laboratory experiments on samples of mantle-like composition (Akimoto and Fujisawa, 1968; Ringwood and Major, 1970). In each case, a key to our current view of the Earth's origin and state was established.

It may seem at first surprising that materials of such different size, from thousand kilometer structures in Earth to laboratory samples as small as a few microns – a range of 12 orders of magnitude – may be compared at all. (Though they are usually ignored for bulk samples, if one takes surface effects into account, the comparison can be extended down to the nanometer scale.) Actually, the basic approach is not unique to geophysics and forms the basis for understanding the structure and evolution of stars and other planets, including exoplanets (Kippenhahn et al., 2012; Valencia et al., 2006). The theoretical basis for spanning the range of length scales from atoms to planets lies at the heart of thermodynamics and statistical mechanics: the prediction that the bulk equilibrium properties of materials should not depend on the size of the sample. There are deep connections to seismology, as well: the analysis of the normal modes of vibration of an atomic lattice leads to concepts of dispersion and elastic-wave velocity that can be linked directly to analogous seismological problems. Relating the large to the small is essential for uncovering the temperature and composition throughout the Earth's interior. High-pressure devices and theoretical simulations figuratively transport us to the inaccessible interior, giving us a unique window into its nature.

From the point of view of materials theory, Earth is a particularly challenging object because it consists of solids and fluids (condensed matter) at moderate to high pressures. Unlike the gases that make up planetary atmospheres, the temperature-dependent constitutive relations between stress, strain, and strain rate (pressure, density, and deformation rate for a fluid) cannot be written down analytically. Much of the effort in mineral physics is devoted to discovering these constitutive relations, either by experimental measurement or by quantum mechanical theory.

The solid state is also complex in that elements organize themselves into multiple phases of different composition and crystal structure (i.e., geometric arrangement by which the atoms are packed together to form the crystal). Each phase has distinctive physical and chemical properties, and its behavior must be understood separately and in combination with other phases. The exploration of high pressure continues to be one of the frontiers of mineral physics, including the challenge of measuring physical properties in the laboratory at conditions of the Earth's interior and the ongoing discovery of new solid phases.

Perhaps, the most challenging aspect of the solidity of materials making up the mantle is that it imposes limitations on our ability to scale from the laboratory to the Earth. These limitations arise from the heterogeneity inherent even in the purest sample in the form of grain boundaries and the differences in size, shape, and orientation of the constituent grains. So, for example, it is not possible to uniquely compute the seismic velocity of a rock from the properties of its constituent single crystals, although rigorous bounds can be formulated if the grains are randomly oriented. An exact computation requires complete specification of the grain geometry. Although usually not the case for Earth materials, the bounds can be far apart in the presence of significant mechanical heterogeneities such as partial melts or cracks. More generally, some physical properties such as attenuation and scattering depend essentially on length scale and often in ways that are difficult to predict.

The significance of the length scale of heterogeneity is intimately linked to the timescale of deformation. All materials contain defects, such as dislocations, interstitial atoms, and vacancies. When deformed at very high ('infinite') frequency, the types and concentrations of defects are of little consequence, and the material deforms elastically because the defects are frozen in place. Seismic waves have much longer periods of deformation however: roughly 14 orders of magnitude greater than those of atomic vibrations. At these timescales, defects can move in response to deformation, leading to anelastic behavior with the absorption of mechanical energy and lowering of the elastic wave relative to the elastic limit. In the limit of much longer periods of deformation, such as those that characterize mantle convection, the deformation is entirely viscous and dominated by the motion of defects.

The nature and degree of anelasticity depends in detail on defect types (point defects, dislocation, and grain boundary), concentrations, and mobilities. Anelasticity is thus not necessarily a state function, in the usual thermodynamic sense, and can depend on the past history of the sample. This presents severe challenges to experimental control and characterization and to our ability to relate the results to the Earth where the deformation history that the materials have undergone may be very different from those prepared in the laboratory. On the other hand, the fact that anelasticity depends on so many more variables than the elastic-wave velocity presents the opportunity for further characterizing the nature of the Earth's interior in ways that are not possible through the analysis of the elastic limit alone. These comments apply to nonequilibrium properties more generally, such as thermal conductivity, chemical diffusivity, and effective viscosity, among others: properties that are important not only because they play crucial roles in controlling the Earth's evolution but also because they allow minerals to approach the condition of thermodynamic equilibrium on which we focus. Nonequilibrium properties of minerals and rocks are beyond the scope of this chapter.

Here, we highlight the relationship between mineral elasticity (and density) and Earth structure. Our approach will be that of the forward problem. We begin with the fundamentals of mineral elasticity, including the basic theory of lattice vibrations, dispersion and normal modes, and its relationship to the various experimental probes of elasticity, to the thermodynamic properties of minerals, and to the underlying quantum mechanics of bonding. The discussion of the elasticity of rocks includes an outline of the theory of composites as applied to the elastic constants and the essentials of anelasticity (i.e., at quasiequilibrium). Finally, we consider the issue of scaling in length and time, from the laboratory to the Earth. We end with

thoughts on the prospects for the inverse problem, that is, formally inverting seismological observations for quantities such as the temperature and compositional fields at depth via knowledge of the materials properties.

1.26.2 Mineral Elasticity

1.26.2.1 Overview

In the limit of ideal crystals and small deformations, the elasticity of solids is most usefully viewed in the context of the vibrational modes of crystalline structures. The theory of the dynamics of perfect crystals is our most powerful way of envisioning length scaling. It gives us a formally exact means of relating the elastic-wave velocity of samples ranging in size from sub-micrometer to – in principle – infinite size, limited only by considerations of surface effects at small scales and of self-gravitation (and, implicitly, strength) as we approach planetary size. The material can be treated as a continuum at large scales, and its properties derived from the consideration of the forces acting between atoms, that is, from a description at the smallest of scales. In particular, the seismic-wave velocities of a perfect crystal are determined by the crystal structure and interatomic forces.

The approach of lattice dynamics is also important in geophysics because it underlies our understanding of the influence of temperature on physical properties, including thermal expansion that drives convection of the mantle and core and seismic-wave velocities that provide images of our planet's interior. The theory of thermal conductivity also derives from concepts of phonons, which are the modes of oscillation of atoms in a crystal (analogous to the normal modes of the Earth). The theory of lattice dynamics is well developed, and there are many excellent texts covering the subject more deeply than we can here (Ashcroft and Mermin, 1976; Born and Huang, 1954; Dove, 1993). In addition to illustrating the connection between microscopic and macroscopic properties, our goals are to illustrate the relationship between experimental and geophysical measurements of elastic-wave velocities.

1.26.2.2 One-Dimensional Lattice Dynamics and the Continuum Limit

A good illustration of these concepts is provided by the one-dimensional (1D) normal modes of vibration of a linear chain of identical atoms of mass m separated by a distance a and connected with Hookean springs, for which the relationship between force F and displacement u is $F=Ku$, where K is the force constant (Figure 1). The potential energy is a quadratic function of the displacement of the atoms, and the equations of motion are

$$m\frac{\partial u_n^2}{\partial t^2} = K\left[(u_{n+1}-u_n)^2 + (u_{n-1}-u_n)^2\right] \qquad [1]$$

Here, u_n is the displacement of the nth atom from its ideal lattice site, located at the position na. Substituting a traveling-wave solution for u_n as a function of position and time, $u=A\exp[i(\omega t-kx)]$, we find the dispersion relation (Figure 1)

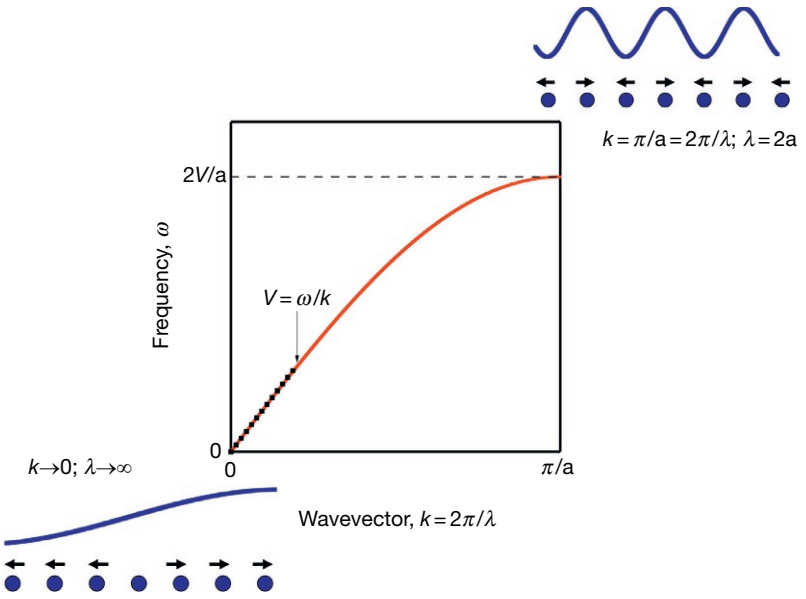

Figure 1 Phonon dispersion relation for the one-dimensional lattice (1D) (red line) indicating the relationship to the acoustic velocity as the slope at the origin (dashed black line). Schematically illustrated are vibrational modes, with arrows and blue curves indicating the sense of displacement of the atoms (blue circles) in the limits of long wavelengths (lower left) and of the shortest wavelengths (upper right). The group velocity (slope of the ω–k curve) vanishes at the Brillouin zone edge, $k=\pi/a$, because shorter wavelengths cannot be propagated across the discrete row of atoms; consequently, there is a standing wave with no wave-energy propagation for $\lambda=2a$. In detail, the ω–k curve (branch) is actually a collection of N distinct points, corresponding to the N normal modes (standing waves) of a 1D chain of N atoms; for N large enough (bulk sample), the set of points is indistinguishable from a continuous line. Reproduced from Stixrude L and Lithgow-Bertelloni C (2012) Geophysics of chemical heterogeneity in the mantle. *Annual Review of Earth and Planetary Sciences* 40: 569–595.

$$\omega = 2\sqrt{\frac{K}{m}}\left|\sin\left(\frac{ka}{2}\right)\right| \quad [2]$$

where ω is the frequency (in rad s^{-1}), $k=2\pi/\lambda$ is the wave number (in rad m^{-1}), and λ is the wavelength (in m $cycle^{-1}$) of the normal mode of vibration. (In 2D and 3D, the wave vector specifies propagation direction and its magnitude gives the wave number.) The phase velocity describing the propagation speed of a given wavelength is given by $V_\phi=\omega/k$, whereas the group velocity that describes the propagation speed of a wave packet (i.e., many different wavelengths and hence the wave energy) is $V_G=\partial\omega/\partial k$. In general, the linear monatomic chain is thus dispersive, with wavelength-dependent velocities and specifically $V_G<V_\phi$ (i.e., a low-pass filter; longer waves travel faster than shorter waves, thereby 'dispersing' an originally compact wave packet into a more extended displacement bundle).

At long wavelength, as $k\to 0$, the group and phase velocities are the same (which means there is no dispersion – i.e., spreading out of a wave packet):

$$V = a\sqrt{\frac{K}{m}} = \sqrt{\frac{M}{\rho}} \quad [3]$$

where the last equality emphasizes the relationship with the seismic-wave velocity expressed in terms of an elastic modulus $M=K/a$ and a density $\rho=m/a^3$. Here, M is the longitudinal modulus, since propagation and polarization are parallel for the present 1D example. The motion described by eqns [2] and [3], with $\omega\to 0$ as $k\to 0$, is referred to as an acoustic mode.

Equation [3] applies to the continuum limit, with wavelengths being much larger than interatomic spacings, as is the case for seismic waves. Indeed, it agrees with our intuitive notions about seismic-wave velocities. As we increase the strength of the interatomic forces, the velocity increases, for example, in the case of increasing pressure. Also, as we increase the mass of the atoms, the velocity decreases, for example, in the case of iron enrichment.

What do the normal modes look like in the limit of the wavelength approaching twice the interatomic spacing, $k\to\pi/a$? This is of interest because shorter wavelengths cannot be supported by the chain of discrete atoms; in fact, normal modes with wavelengths less than twice the interatomic spacing are indistinguishable from those within the wave number range $k=0$ to π/a. (This limitation is identical to the Nyquist theorem encountered in Fourier and signal theory, which specifies that at least two samples per wavelength are needed to characterize a wave, and also corresponds to the Heisenberg uncertainty principle in quantum mechanics.) This range of wave numbers defining the first Brillouin zone in reciprocal (wave number or Fourier transform) space contains complete information on all the normal modes that the chain of atoms can experience. At the Brillouin zone edge ($k=\pi/a$), the motion of each atom opposes its neighbors (**Figure 1**): each bond is stretched or compressed by the same amount, producing the maximum frequency $\omega = 2\sqrt{(K\ m^{-1})} = 2V/a$.

The particulate nature of matter thus produces velocity dispersion as wavelengths approach atomic (or unit cell) dimensions, well below the continuum range. This is reflected in the nonlinear form of eqn [2] and, for example, the difference between the Brillouin zone-edge frequency and the linear extrapolation of eqn [2] to the Brillouin zone edge $\omega=\pi V/a$. This type of dispersion is negligible in the usual geophysical context and, for ideal crystals, scaling from laboratory samples to geophysical length scales is essentially exact. From eqn [2], we find that even for length scales corresponding to very small grains (1 μm), the dispersion is only about one part in three thousand. This unity of length scales is modified by heterogeneity (e.g., grain boundaries, as well as variations in mineral phase abundances, compositions, and orientations) and anelasticity in real (nonideal) samples.

1.26.2.3 Experimental Methods

Experimental probes of the elastic-wave velocities have characteristic wavelengths that, while orders of magnitude smaller than those of seismic waves, lie well within the continuum, infinite-size limit of ideal crystals. Brillouin spectroscopy is most closely connected to the phonon spectrum (Duffy et al., 1995; Jackson et al., 2000; Marquardt et al., 2009; Murakami et al., 2009; Sinogeikin and Bass, 2000; Weidner et al., 1982). Here, one measures the normal-mode frequency of the acoustic branch at a small but finite value of the wave number related to the wavelength of the (generally visible) light used to probe the sample, with the ratio of frequency to wave number yielding the elastic-wave velocity. The wave number is given by the magnitude of the scattering vector (i.e., the projection of the light's wavelength onto the direction of acoustic-wave propagation in the crystal) through a formula analogous to Bragg's law for x-ray diffraction. The frequency is observed as a Doppler-like shift of the scattered relative to the incoming light, and Brillouin spectroscopy can be thought of as the acoustic-mode analog of Raman spectroscopy, the latter scattering off the optic modes to be described later. In impulsive stimulated scattering, a time-domain version of Brillouin spectroscopy, a phonon is excited by one laser and scatters light from a second laser, yielding information on elasticity as well as thermal conductivity (Abramson et al., 1999; Brown et al., 1989; Crowhurst et al., 2008; Zaug et al., 1993). Nuclear resonant inelastic x-ray scattering is also sensitive to phonon energies over a range of wave vectors, so can yield information about sound velocities (Fiquet et al., 2001; Mao et al., 2001).

Similarly, resonant ultrasound spectroscopy and ultrasonic interferometry determine the normal-mode frequencies of a macroscopic crystal (megahertz for typical experimental sample sizes) and are thus analogous to normal-mode studies of the Earth (Anderson and Isaak, 1995; Goto et al., 1976). Other ultrasonic methods are analogous to body-wave seismology: an acoustic pulse of frequency megahertz–gigahertz is generated via a transducer and the travel time across the sample measured; multiple reflections and interference are used to maximize precision (Chantel et al., 2012; Jackson and Niesler, 1982; Rigden et al., 1991; Spetzler, 1970; Yoneda, 1990). High frequencies are essential so that the acoustic wavelength (10 μm–1 mm) is much smaller than the size of the sample (~1 mm for *in situ* high-pressure measurements).

All of these methods involve small ('infinitesimal')-amplitude waves. In addition, two classes of finite-compression methods are available: dynamic (shock wave) and static. In the first, a large-amplitude deformation wave is generated by the

impact of a projectile or a laser pulse into the sample, which is then compressed on a timescale of *ns*. The velocity of the resulting shock wave is then approximately equal to the longitudinal-wave velocity at low pressures (below the dynamic yielding point) and to the bulk-sound velocity at higher pressures (thermal and other corrections can be made to obtain more exact results). Above the dynamic yielding point, the shock front moves at close to the high-pressure bulk-sound velocity (i.e., fluid-like response), but rarefaction waves – inevitably generated at all free surfaces of the sample – propagate into the shock-loaded state: this is measurable, with the decompression traveling at the longitudinal- (compressional-) wave velocity relative to the shocked material. The bulk-sound velocity (V_B) and longitudinal-wave velocity (V_P) can thus be probed dynamically, and the shear-wave velocity (V_S) is obtained from the relation (Brown and McQueen, 1986; Duffy and Ahrens, 1992; Nguyen and Holmes, 2004)

$$\frac{4}{3}V_S^2 = V_P^2 - V_B^2 \qquad [4]$$

The bulk-sound velocity can also be determined in static experiments from the equation of state (Duffy and Wang, 1998; Jeanloz and Thompson, 1983; Stixrude et al., 1992). Using a diamond anvil cell or other high-pressure device, one measures the volume (or density ρ) as a function of pressure via very slow (minutes–days) stepwise compression: x-ray diffraction is used to determine the compression, for example. The slope of the relationship yields the isothermal bulk modulus $K_T = (\partial P/\partial \ln \rho)_T$ that is related to V_B through

$$V_B = \sqrt{\frac{K_S}{\rho}} \qquad [5]$$

and the correction from the isothermal to the adiabatic (K_S) bulk modulus, which is small at room temperature.

One of the important conclusions to arise from these various probes of material elasticity is that frequency dependence is essentially undetectable over eight orders of magnitude: Shear- and longitudinal-wave velocities are indistinguishable from 100 THz (Brillouin) to 1 MHz (ultrasonic), and the bulk-sound velocity is invariant from 100 THz to the essentially zero-frequency (DC) measurements of static compression. In contrast, the Earth shows measurable frequency dependence of the shear-wave velocity over a much narrower range of lower frequencies (hertz to millihertz) (Dziewonski and Anderson, 1981). The comparison with laboratory studies suggests that the magnitude of shear-wave attenuation – and resulting dispersion – is larger at the low frequencies of seismic observations than at the higher frequencies of laboratory measurements; over yet longer timescales, the response of Earth materials to shear stresses merges into the viscous relaxation that controls tectonic motions. At the same time, changes in volume (e.g., due to pressure changes) create shear stresses and strains inside a composite medium (such as a polycrystalline or polymineralic rock), resulting in bulk attenuation due to the coupling with shear attenuation. The upshot is that both compressional and shear waves (and spheroidal and toroidal normal modes) can show evidence of attenuation and consequent dispersion at the low frequencies of seismic observations.

1.26.2.4 3D Lattice Dynamics: Polarization and Anisotropy

Only longitudinal elastic modes are possible in one dimension: shear elastic modes are higher-dimensional phenomena because the polarization (direction of atomic displacement) differs from that of propagation (wave vector). In three dimensions, there are three acoustic branches, one corresponding to the P-wave and two to the S-waves (Figure 2; the optic modes are discussed later). All solids support both longitudinal and shear waves. In the case of isotropic solids (glasses) and liquids, the two shear branches are indistinguishable (degenerate) despite corresponding to perpendicular polarizations. (Just as at low-enough deformation rates solids flow plastically, at high-enough frequencies, fluids transmit shear waves over finite distances.) For nonisotropic media (crystals and liquid crystals), the two shear branches are in general distinct, although they may be degenerate along certain high-symmetry directions (the two shear branches represent crystallographically orthogonal polarizations but, depending on crystal structure and propagation direction, do not in general represent exactly perpendicular displacements).

Anisotropy, the variation of elastic-wave velocity with propagation and polarization directions, is governed by the fourth-rank elastic-constant tensor, c_{ijkl} (Kosevich et al., 1986; Wallace, 1972). The polarizations and original slopes of the three acoustic branches for wave vector $\boldsymbol{k}$ are given by the Christoffel equation:

$$\rho V^2 = c_{ijkl}\hat{w}_i\hat{k}_j\hat{w}_k\hat{k}_l \qquad [6]$$

where w_i is the polarization vector and the carets indicate unit vectors. We have used the Einstein notation: summation over repeated subscripts, and each subscript takes on each of its values, $i = 1, 2, 3$ (e.g., x, y, and z directions). The symmetry of the elastic-constant tensor reflects that of the point group of the crystal (Nye, 1985). For an isotropic solid (glass), there are only two independent elastic constants, which may be taken as the bulk and shear moduli. For cubic crystals, there are three, c_{11}, c_{12}, and c_{44}, referred to as longitudinal, off-diagonal, and shear, respectively, and as many as 21 for the lowest-symmetry point group (triclinic crystals). Evaluating eqn [6] for pure P-wave propagation ($k = w$) in cubic symmetry,

$$\frac{\rho V_P^2}{c_{11}} = 1 + 2A\left(k_1^2k_2^2 + k_1^2k_3^2 + k_2^2k_3^2\right) \qquad [7]$$

where the anisotropy factor

$$A = \frac{2c_{44} - (c_{11} - c_{12})}{c_{11}} \qquad [8]$$

completely determines the P-wave anisotropy (Karki et al., 1997b). We have used the Voigt contraction for the indices of the elastic constants: $11 \to 1$, $22 \to 2$, $33 \to 3$, $12 \to 6$, $13 \to 5$, $23 \to 4$. One can show that A also determines the azimuthal and polarization shear anisotropy. The right side of eqn [7] gives $1 + 2/3A$, $1 + 2/9A$, and 1 for propagation along [1 1 1], [1 1 0], and [1 0 0], respectively.

We can evaluate the likely magnitude of single-crystal anisotropy if we assume that the interatomic forces are central and between nearest neighbors only and we neglect coupling between strain and vibrational modes. The elastic-constant tensor is then (Gieske and Barsch, 1968)

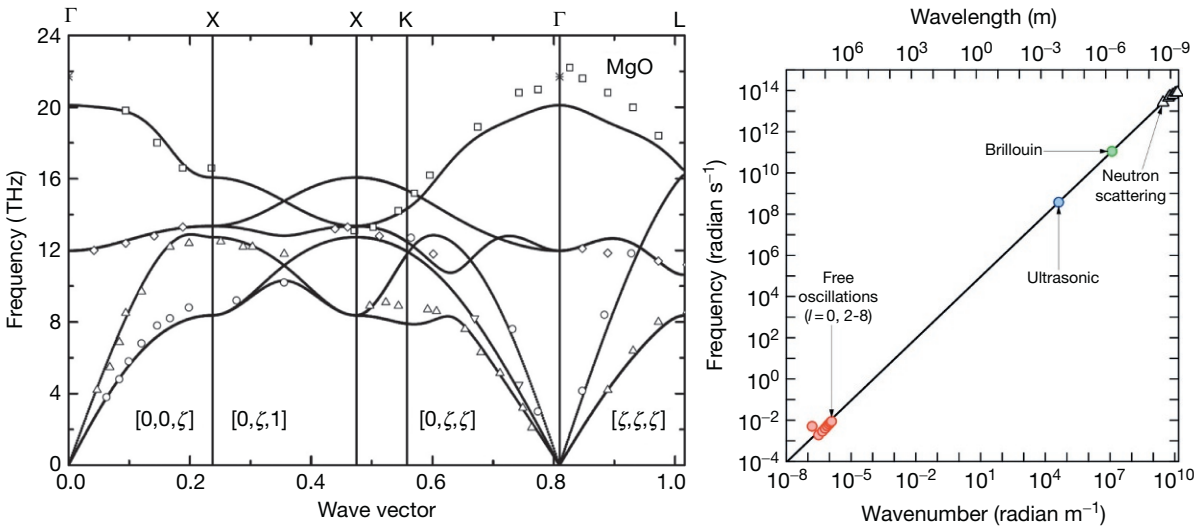

Figure 2 (left) Phonon dispersion curves of periclase (MgO) according to density-functional theory (lines) and experiment (symbols), showing the three acoustic modes with zero frequency at the Brillouin zone center (Γ point) and the three optic modes with finite frequency at Γ (some of the branches are degenerate – overlap – in all directions shown except for [0, ζ, ζ]). The direction of the wave vector is indicated in square brackets in each panel, the magnitude of the wave vector is given in units of $Å^{-1}$, and high-symmetry directions, defined in terms of the wave vector, are given conventional labels along the top (Lax, 1974). From Parlinski et al. (2000). (right) The longitudinal acoustic (LA, higher frequency) branch in the Γ–X direction plotted on a log–log scale: the black line and triangles have the same meaning as in the left-hand figure. Also shown are Brillouin spectroscopic measurements of the LA mode frequency at zero pressure plotted at the wave number of the laser probe (wavelength = 514.5 nm) and the observed frequency (green symbol) (Sinogeikin and Bass, 2000), the ultrasonic measurement of the P-wave velocity at zero pressure (blue symbol) (Jackson and Niesler, 1982), and the lowest-order spheroidal free oscillation modes of the Earth (red symbols) (Masters and Widmer, 1995). Reproduced from Stixrude L and Lithgow-Bertelloni C (2012) Geophysics of chemical heterogeneity in the mantle. *Annual Review of Earth and Planetary Sciences* 40: 569–595.

$$c_{ijkl} = (K - P)\frac{9}{z}\sum_{\alpha=1}^{z} \hat{r}_i^{\alpha}\hat{r}_j^{\alpha}\hat{r}_k^{\alpha}\hat{r}_l^{\alpha} \qquad [9]$$

where P is pressure, K is the bulk modulus, z is the coordination number, and $\hat{\mathbf{r}}^{\alpha}$ is the unit vector between an atom and its nearest neighbor α; the sum is over all nearest neighbors. For body-centered cubic (bcc) and face-centered cubic (fcc) crystal structures, eqn [9] yields positive values of A and therefore greater velocities along [1 1 1] and [1 1 0] than along [1 0 0]. The magnitude of the anisotropy is large: for fcc, $A = ½$, yielding peak-to-peak variations in the P-wave velocity of 30%. This simple model has been applied to oxides based on the argument that the elasticity is primarily governed by the oxygen sublattice and oxygen–oxygen repulsion, with the cations largely playing a passive, charge-balancing role.

The relative importance of central versus other interatomic forces can be deduced by comparing the elements of the elastic-constant tensor to the predictions of the Cauchy relations, which apply for purely central forces (**Figure 3**). (Angle-dependent and three-body forces are examples of noncentral interactions between atoms; Weiner (1983) showed more generally that for centrosymmetric crystals, the harmonic elastic moduli satisfy the Cauchy relations if the electron charge density follows the (homogeneous) deformation of the underlying lattice of nuclei.) For example, in a cubic material, the Cauchy relations predict

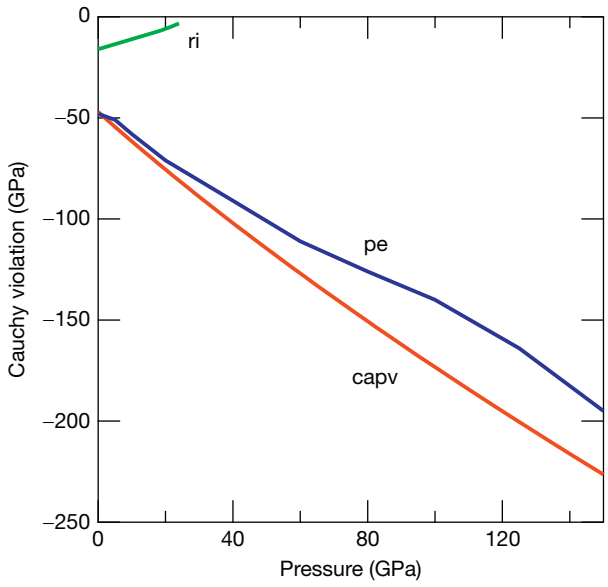

Figure 3 Violation of the Cauchy relation (eqn [10]) of three cubic minerals according to density-functional theory: spinel-structured Mg_2SiO_4, ringwoodite (ri); NaCl-structured MgO, periclase (pe); and perovskite-structured $CaSiO_3$ (capv) (Karki and Crain, 1998; Karki et al., 1997b; Kiefer et al., 1997). Reproduced from Stixrude L and Lithgow-Bertelloni C (2012) Geophysics of chemical heterogeneity in the mantle. *Annual Review of Earth and Planetary Sciences* 40: 569–595.

$$c_{12} - c_{44} = 2P \qquad [10]$$

In the case of MgO, often considered to be a prototypical ionic solid for which one expects central forces to be dominant, eqn [10] is increasingly violated with increasing pressure (Isaak et al., 1990; Karki et al., 1997b). This shows that the interatomic forces become increasingly noncentral with increasing pressure, as expected from comparisons of elastic moduli among several oxides of the same crystal structure. One consequence of this change in forces is that the sign of the elastic anisotropy changes with increasing pressure (Figure 4). Whereas at low pressure, A is large and positive, in accord with expectations based on eqn [9] and the fcc oxygen sublattice of MgO, at high pressure, A becomes negative, with a magnitude at the core–mantle boundary greater than that at ambient pressure. The change in sign of A corresponds to a change in the fastest and slowest directions: [1 1 1] is fastest for P-wave propagation at ambient pressure, whereas [1 0 0] is fastest at the core–mantle boundary. Other minerals also show strong pressure dependence of the magnitude and sense of the anisotropy (Karki et al., 2001).

Considerations of mechanical stability place constraints on the relative magnitude of the elastic constants of any material, whether single crystals or rocks. For isotropic symmetry, the stability condition is simply that the bulk and shear moduli be positive definite. For cubic symmetry, the conditions are

$$c_{44} > 0, \quad c_{11} > |c_{12}|, \quad c_{11} + 2c_{12} > 0 \qquad [11]$$

and for hexagonal symmetry,

$$c_{44} > 0, \quad c_{11} > |c_{12}|, \quad (c_{11} + c_{12})c_{33} > 2c_{13}^2 \qquad [12]$$

The more general statement from which stability conditions for arbitrary symmetry derive is that the principal minors of the elastic-constant matrix (Voigt notation) must be positive definite (Nye, 1985). Elastic instabilities place fundamental constraints on the phases that exist in the Earth. For example, it has been argued that the predicted elastic instability in the bcc phase of iron means that this phase cannot exist in the inner core, with important implications for the origin of anisotropy in this region (Stixrude et al., 1994). More recent experimental and theoretical work shows that there is no evidence of bcc Fe being stable at inner-core conditions (e.g., Ping et al., 2013).

One of the most fundamental conclusions from experimental and theoretical studies of minerals is that the elastic anisotropy of individual crystals is much larger than that observed seismologically in most parts of the Earth, albeit over much greater length scales ($\sim 10^3$–10^6 m) as compared with crystal dimensions ($\sim 10^{-3}$–10°m). Peak-to-peak azimuthal variation in velocities of 10% or more is typical in mantle and core minerals, as compared with a few percent in the Earth. The single-crystalline anisotropy of some minerals is sufficiently large to produce cusps in the group velocity envelope (Helbig, 1984) (Figure 5). Experimental measurement and prediction of the single-crystal anisotropy is essential because it forms the basis for estimating the anisotropy of rocks and places an upper bound on the observed elastic anisotropy that can be produced by lattice-preferred orientation. Most of the experimental methods discussed previously are capable of measuring the full elastic-constant tensor and therefore the velocity in all directions. These measurements must be made on single crystals. In the case of Brillouin or ultrasonic interferometry, several measurements are necessary, varying the direction of the impulse with respect to the crystallographic axes in order to sample different directions in reciprocal space.

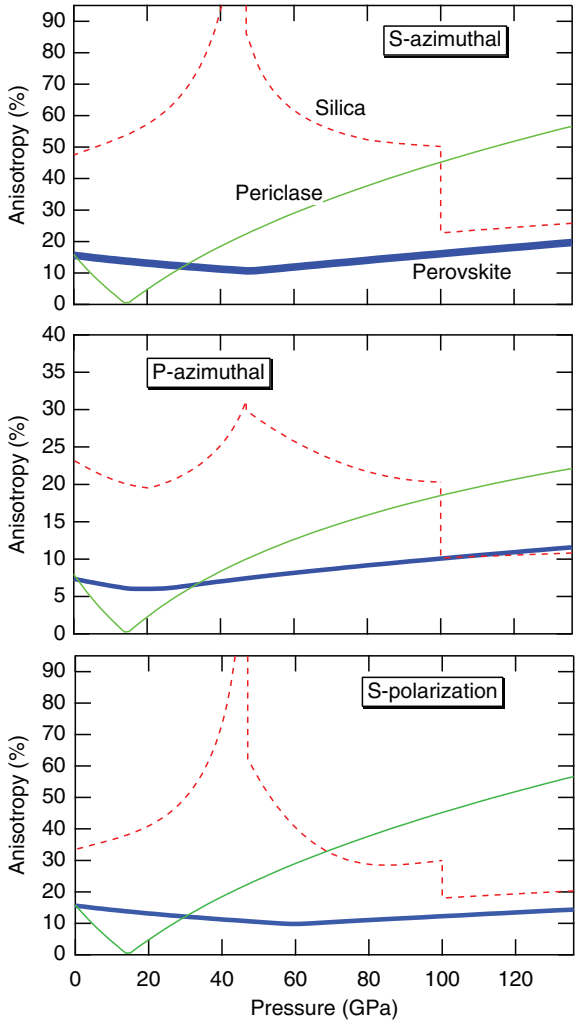

Figure 4 Elastic anisotropy of SiO_2 (red dashed curves), MgO periclase (light green solid), and $MgSiO_3$ perovskite (bold blue solid) according to density-functional theory. P-azimuthal anisotropy and S-azimuthal anisotropy are the differences between the maximum and the minimum P- and S-wave velocities, respectively, over all propagation and polarization directions, and the polarization anisotropy is the maximum difference in velocity between the two S-wave polarizations over all propagation directions. The discontinuous changes in the curve for SiO_2 are due to phase transformations from stishovite to the $CaCl_2$ structure at 47 GPa and to the α-PbO_2 structure at 100 GPa. Breaks in slope in the MgO and $MgSiO_3$ curves represent pressures at which the pattern of anisotropy changes. In the case of MgO, the break in slope near 15 GPa coincides with a vanishing of the anisotropy that is due to a change in sign of the anisotropy factor A (eqn [8]). Reproduced from Stixrude L (1998) Elastic constants and anisotropy of $MgSiO_3$ perovskite, periclase, and SiO_2 at high pressure. In: Gurnis M, et al. (eds.) *The Core-Mantle Boundary Region*, pp. 83–96. Washington, DC: American Geophysical Union.

What is the origin of anisotropy in the mantle and core? There are at least two possible explanations, shape-preferred orientation and lattice-preferred orientation. These two

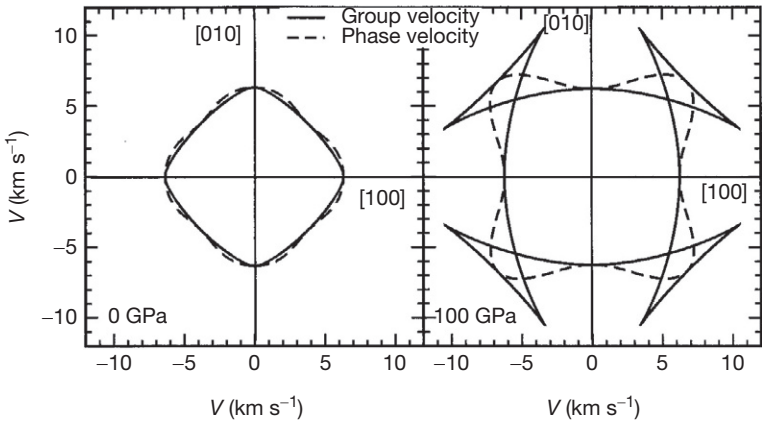

Figure 5 Group velocity (solid curves) and phase velocity (dashed curves) surfaces of S-waves in MgO in the (001) plane at two pressures. The two velocities are close to each other at zero pressure due to relatively weak anisotropy, but they differ substantially at 100 GPa due to relatively strong anisotropy. Reproduced from Kark BB, Stixrude L, and Wentzcovitch RM (2001) High-pressure elastic properties of major materials of Earth's mantle from first principles. *Reviews of Geophysics* 39: 507–534.

mechanisms for generating anisotropy in a polycrystalline aggregate arise in principle from very different sets of processes and so carry important implications for our understanding of mantle dynamics and evolution. In the case of lattice-preferred orientation, anisotropy originates in the elastic anisotropy of the constituent crystals and is in general present for single- as well as multiphase aggregates. Since the single-crystal anisotropy can be large, it is natural to consider lattice-preferred orientation as the primary explanation in many cases (Figure 4). Knowledge of the single-crystal elastic anisotropy is not sufficient to determine that of a polycrystalline aggregate, however. For this, one must also know the texture, that is, the orientations of all the crystals in the aggregate.

Shape-preferred orientation arises from an inhomogeneous distribution of phases with different elastic properties. Anisotropy due to shape-preferred orientation scales with the contrast in physical properties between the phases and therefore applies only to multiphase aggregates (composites). It can be large, for example, in cracked or partially molten rock. In the limit of large scales, variations of rock types (lithologic variations) can induce anisotropy that affects seismic waves.

Presumably, both shape-preferred orientation and lattice-preferred orientation cause seismic anisotropy within the Earth. That the observed anisotropy is quantitatively much smaller than could be expected based on laboratory and theoretical studies of individual minerals and mineral aggregates strongly suggests that the seismological information is spatially aliased. That is, the seismic wavelengths ($\sim 10^3$–10^6 m) are typically so much longer than the dimensions of crystals, or even lithologic variations, that they reflect only a broad spatial average of the true heterogeneity and anisotropy at depth.

1.26.2.5 Nontrivial Crystal Structures, Optic Modes, and Thermodynamics

Lattice vibrations are geophysically significant not only for their connection to elasticity but also because they govern most thermodynamic properties of Earth materials, including the magnitude of entropy and heat capacity as well as the temperature dependence of the elastic constants. Most of the temperature dependence of the energy of a crystal comes from the increasing energy of atomic vibrations with increasing temperature. The derivation of the internal energy due to lattice vibrations is outlined in the texts listed earlier. Here, we seek an intuitive understanding, simply quoting the result for the internal energy associated with atomic vibrations:

$$U_{\text{vib}} = \frac{1}{2}\sum_i \hbar\omega_i + k_{\text{B}}T\sum_i \frac{\hbar\omega_i/k_{\text{B}}T}{e^{\hbar\omega_i/k_{\text{B}}T} - 1} \qquad [13]$$

where $\hbar$ is Planck's constant divided by 2π, k_{B} is Boltzmann's constant, and the sums are over all $3N$ vibrational modes (in 3D) with N being the number of atoms in the crystal. The first term is due to zero-point motion and can be attributed to the Heisenberg uncertainty principle. The second term is the product of the energy of a particular vibrational mode ($\hbar\omega$) and the probability of excitation ('occupation') of that mode. The probability of occupation may appear unfamiliar because it is derived from the appropriate quantum (Bose–Einstein) statistics, but it does reduce to the Boltzmann factor $\exp(-\hbar\omega/kT)$ in the limit of high temperatures. The probability of occupation says that while very high-frequency modes (such as the stretching of the O—H bond) will barely be excited until one reaches mantle temperatures, the part of the acoustic branch near the Brillouin zone origin (i.e., wavelengths much larger than the interatomic spacing) is already fully excited even at room temperature.

Eventually, all vibrational modes are fully excited, and the second sum on the right-hand side approaches a constant, equal to the number of modes ($3N$). In this Dulong–Petit limit, the vibrational energy is linear in temperature, and the heat capacity at constant density approaches a constant value

$$C_\rho = \left(\frac{\partial U_{\text{vib}}}{\partial T}\right)_\rho \rightarrow 3Nk_{\text{B}} \qquad [14]$$

or 1188 J K^{-1} g^{-1} for a mean atomic mass typical of the mantle (21 g mol^{-1}). Vibrational frequencies of Earth materials are such that the Dulong–Petit limit is obeyed to within a few percent at temperatures typically reached beneath the crust.

A practical difficulty in using eqn [13] is that all the vibrational frequencies must be known, which is rarely the case for mantle phases, particularly at high pressure. By reformulating as a sum over energies rather than states, with the energy of a mode of frequency ω_ι being given by $\hbar\omega_\nu$ we reestablish the connection with the analysis of phonon dispersion outlined earlier and develop a useful starting point for approximating the sums. The vibrational energy can then be written as

$$U_{\text{vib}} = k_{\text{B}}T\int_0^\infty \left(\frac{1}{2}+\frac{1}{e^{\hbar\omega/k_{\text{B}}T}-1}\right)\frac{h\omega}{k_{\text{B}}T}g(\omega)\,\mathrm{d}\omega \qquad [15]$$

where the vibrational density of states $g(\omega)$ (see Figure 2) is normalized such that

$$3N = \int_0^\infty g(\omega)\,\mathrm{d}\omega \qquad [16]$$

The power of this reformulation is illustrated by one of the simplest approximations for $g(\omega)$, due to Debye:

$$g(\omega) = 9N\omega^2\omega_{\text{D}}^{-3} \qquad [17]$$

This is derived by treating the material as a homogeneous continuum: that is, ignoring optic modes (described later) and approximating the acoustic phonon branch as linear with slope equal to the acoustic velocity (see eqn [3]; for this case without dispersion, $\omega \propto k$, and because $g(\omega) \propto k^2$ in 3D, it is proportional to ω^2 as in eqn [17]). The quantity ω_{D} is the Debye frequency, obtained by linearly extrapolating the acoustic branch to the Brillouin zone edge and ensuring that eqn [16] is satisfied. (Ensuring that only $3N$ normal modes, i.e., $3N$ degrees of freedom, are present for a crystal of N atoms in 3D takes into account the atomic constituents of the medium. It was Debye's genius to realize that a self-inconsistent model of a homogeneous continuum with underlying atomic structure would lead to a physically sound result.) In three dimensions, the velocity is replaced by an appropriate average over all directions and polarizations and the bond length by the mean atomic spacing. The squared-frequency dependence arises from the assumptions that the density of vibrational states is uniform in reciprocal space and that the first Brillouin zone is a sphere. The Debye approximation captures much of the essential features of the heat capacity, including the observation that it vanishes at zero temperature as T^3 and approaches the Dulong–Petit limit at high temperature.

Simple approximations to the vibrational density of states, like the Debye approximation, do not explicitly account for the structural complexity characteristic of most Earth materials: in particular, several different atoms are typically present in each unit cell of the crystal structure (e.g., Mg and O in MgO). What influence do these complexities have on the normal modes of vibration? The essential features are captured by a linear chain but now with two different spring constants (see also Kieffer, 1979) (Figure 6). The broken symmetry doubles the unit cell (i.e., two atoms, one of each color in each unit cell vs. one atom per unit cell in the monatomic linear chain) and halves the first Brillouin zone. The relationship of the monatomic and diatomic unit cells in reciprocal space is one of folding the phonon branches so that the vibrational mode that appeared on the Brillouin zone edge in the monatomic case is now folded back to the Brillouin zone center. This is significant

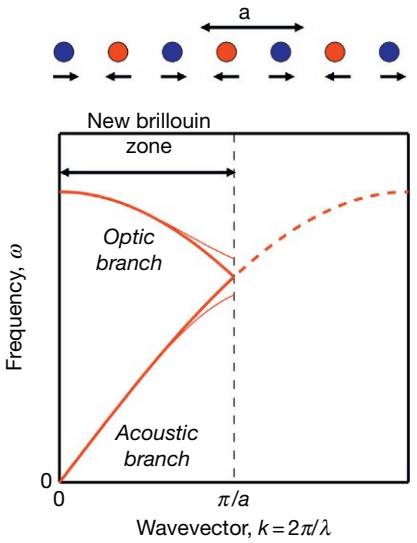

Figure 6 Phonon dispersion curve in a 1D lattice with two types of atoms. The unit cell dimension a is doubled compared with the monatomic case, which halves the size of the reciprocal-space Brillouin zone and folds the dispersion curve, producing an optic branch. The pattern of vibration of the optic mode at zero wave vector is illustrated (top); note that each unit cell has the identical pattern of vibration. The thin solid lines schematically illustrate the opening of an acoustic–optical gap that is produced if the lattice contains two different force constants or if the atoms have different masses. Reproduced from Stixrude L and Lithgow-Bertelloni C (2012) Geophysics of chemical heterogeneity in the mantle. *Annual Review of Earth and Planetary Sciences* 40: 569–595.

because now, we have a vibrational mode of finite frequency at the Brillouin zone center; as this can be observed with long-wavelength probes such as visible light, it is called an optic branch. In general, there are $3n$ mode frequencies at each wave number k in a 3D crystal structure having n atoms per unit cell. To be precise, we refer to the 'primitive' (smallest and irreducible) unit cell throughout this text. Other definitions of the crystallographic unit cell are often used for convenience.

Now, consider what happens when the difference in the two spring constants begins to grow or the masses of the two atoms in the unit cell are allowed to differ (Figure 6). The frequencies of the two normal modes at the Brillouin zone edge begin to separate, as is seen by considering the patterns of vibration. This zone-edge splitting appears whenever the material has bonds of different strength. So, for example, the contrast between the strong Si—O bond and the weaker inter-tetrahedral forces in quartz causes large zone-edge splittings and a clear separation of acoustic and optic modes. Periclase, for which the contrast in bond strengths is much less, shows almost no acoustic–optic gap (in detail, nonnearest neighbor and noncentral forces open a gap even in periclase along certain high-symmetry directions; electron-polarization effects can also play an important role in shifting longitudinal-relative to transverse-optic modes).

In any case, at a given wave vector, we always have three acoustic modes and $3n-3$ optic modes (n is the number of atoms in the unit cell), and all the branches have to have zero slope (standing waves) at the Brillouin zone edge, as is also the

case for optic modes at the zone center. It is also known that longer-range interactions add structure to the ω–k dispersion relation: essentially, each successive coordination shell adds a Fourier component to the mode branch (Gonze et al., 1994).

In the limit of no optical gap, the vibrational density of states may be reasonably approximated by the Debye relation (eqn [17]), regardless of how many atoms are in the unit cell, as the main modification of phonon dispersion is Brillouin zone folding. This realization has led to the concept of Debye-like solids, periclase and corundum being prototypical examples (Anderson, 1995). Materials like quartz and those containing hydrogen bonds are typical counterexamples, for which more elaborate models such as those due to Kieffer are more appropriate (Kieffer, 1980). Even when deviations from a Debye-like spectrum are large, the influence on thermochemical properties is not necessarily significant because these depend at high temperature only on low-order moments (weighted averages) of the vibrational density of states (Barron et al., 1957) (**Figure 7**). Deviations are likely to be largest for water-rich hydrous phases, because the stretching frequency for the O—H bond is so much larger than for any other bond thought to be important in the mantle (Williams, 1995). The essential relationship between acoustic and optic branches has also led to the idea of determining an average elastic-wave velocity from a measurement of the appropriate optic mode at the Brillouin zone center (Merkel et al., 2000).

Thermal expansion arises, in a first approximation, from the volume dependence of the vibrational frequencies (quasiharmonic model). This modification of the theory retains the normal-mode description of the frequencies but allows the frequency spectrum to shift with compression. Anharmonicity generally refers to time dependence of the normal modes (e.g., due to mode mixing) and accounts for physical effects such as temperature dependence of the vibrational frequencies at constant volume that are not explained by quasiharmonic theory (Gillet et al., 1996).

As the crystal compresses, bonds generally become stronger; the vibrational frequencies increase; and, from eqn [13], the vibrational energy decreases. The volume dependence of the vibrational energy produces a vibrational pressure that is positive and tends to expand the lattice. The vibrational or thermal pressure is

$$P_{\text{vib}} = \gamma \rho U_{\text{vib}} \qquad [18]$$

where the Grüneisen parameter is defined by

$$\gamma \equiv \frac{1}{\rho}\left(\frac{\partial P}{\partial U}\right)_{\rho} = \frac{\alpha K_{\text{T}}}{\rho C_{\rho}} = \left(\frac{\partial \ln T}{\partial \ln \rho}\right)_{\text{S}} \qquad [19]$$

and the second and third relations are thermodynamic identities. This makes explicit the relationship between thermal pressure and thermal expansivity α and also shows that the Grüneisen parameter controls the magnitude of the adiabatic temperature gradient (right-hand side of eqn [19]). For models of the vibrational density of states with a single characteristic frequency, such as the Debye or Einstein approximations or, more generally, under the Grüneisen approximation that the logarithmic density dependence of all vibrational frequencies is equal, the following relation also holds:

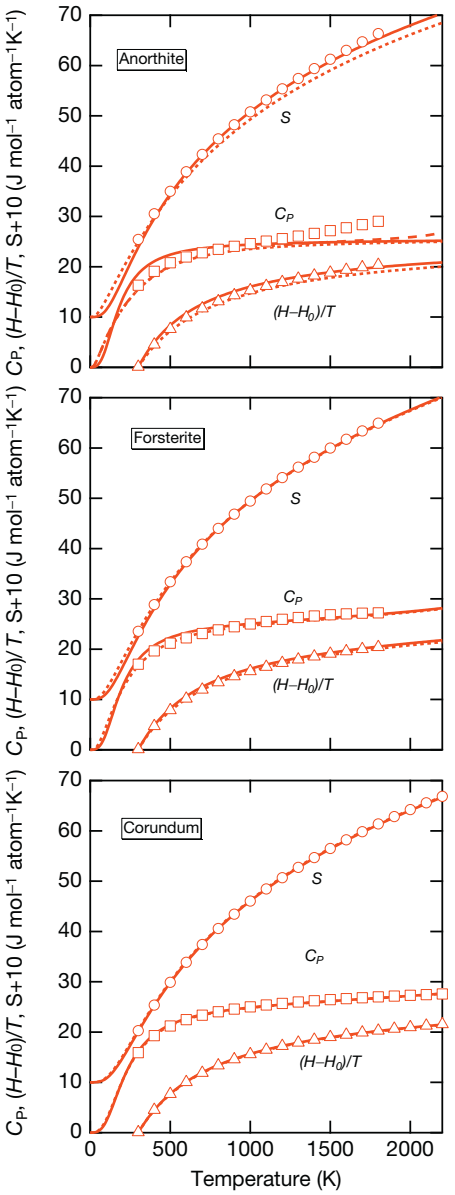

Figure 7 Experimentally derived (Robie and Hemingway, 1995) entropy (circles), heat capacity (squares), and enthalpy function (triangles) compared with (solid lines) Debye model with effective Debye temperature fit to the entropy at 1000 K and (short dashed) the model of Kieffer (1980). For anorthite, the long-dashed line shows the influence of cation disorder on the heat capacity according to the model of Holland and Powell (1998). The entropy is shifted upward for clarity. Reproduced from Stixrude L and Lithgow-Bertelloni C (2005) Thermodynamics of mantle minerals – I. Physical properties. *Geophysical Journal International* 162: 610–632.

$$\gamma = \frac{\partial \ln \omega}{\partial \ln \rho} \qquad [20]$$

establishing the link between quasiharmonic thermal properties such as thermal expansivity and the density dependency of the normal modes of the lattice. The Grüneisen parameter is dimensionless and empirically found to be about 1–3, so is a convenient way of capturing many related influences of

temperature on the physical properties of minerals inside a planet (Mcqueen et al., 1970; Stixrude and Lithgow-Bertelloni, 2005a, 2011; Wallace, 1972). In particular, the thermal expansivity is of geophysical interest because this is the property causing buoyancy, hence driving convection, inside a planet.

To introduce the influence of temperature on the elastic constants, consider the vibrational contribution to the bulk modulus. Taking the density derivative of eqn [18], we see that the temperature dependence of the elastic constants involves not only the Grüneisen parameter, which we assume to depend only on volume, but also the volume derivative

$$q = -\frac{\partial \ln \gamma}{\partial \ln \rho} \qquad [21]$$

where the parameter q is dimensionless and takes on values in the range 1–3 for most mantle phases (McQueen et al., 1967; Stixrude and Lithgow-Bertelloni, 2005a, 2011). The thermal pressure at temperatures above the Debye temperature can be approximated by

$$P_{\mathrm{TH}} \approx 3nRT\gamma\rho \qquad [22]$$

and the thermal contribution to the adiabatic bulk modulus along an isochore is then just the logarithmic density derivative of eqn [22] at conditions of constant entropy

$$K_{\mathrm{TH}} \approx 3nRT\rho\gamma(\gamma + 1 - q) \qquad [23]$$

An important consequence of the fact that $q \geq 1$ for most mantle materials is that the thermal pressure and other thermal effects tend to decrease with compression. For example, the thermal expansivity and the influence of temperature on the elastic-wave velocities decrease with depth, with important implications for mantle dynamics and the interpretation of seismic tomography (Chopelas and Boehler, 1989; Isaak et al., 1992).

Because the Grüneisen parameter plays such a central role in our understanding of the thermal state of the Earth, there has been a great deal of interest in determining its dependence on compression. Many experimental data are consistent with the assumption that q is constant without necessarily requiring it (McQueen et al., 1967). Experimental analyses and theoretical studies suggest that q tends to decrease with compression (Agnon and Bukowinski, 1990; McQueen et al., 1970; Speziale et al., 2001), and analytical forms that capture this behavior have been examined (Jeanloz, 1989; Oganov and Dorogokupets, 2003; Stixrude and Lithgow-Bertelloni, 2005a).

1.26.2.6 Influence of Pressure and Temperature on the Elastic Constants

An important feature of the Earth is that compressions are large – the characteristic pressure is a large fraction of typical zero-pressure values of mineral bulk moduli – and the characteristic temperature is larger than typical vibrational energies of Earth materials. This means that measurements of the pressure and temperature derivatives of the elastic constants near ambient conditions do not suffice to give us a full picture of the variation of these quantities over the conditions of the Earth's interior. Indeed, experimental measurements show that the bulk modulus varies by more than a factor of 2 over the pressure range of the mantle. Such large changes are seen in the density and other properties too and led Birch to apply the theory of Eulerian finite strain to understand the Earth's interior. The theory of finite strain has been generalized to encompass the elastic constants (Davies, 1974) and has recently been reformulated in a thermodynamically self-consistent manner (Stixrude and Lithgow-Bertelloni, 2005a). Only the final results are discussed here.

The variations of the bulk and shear moduli with volume and temperature are, respectively,

$$K = (1+2f)^{5/2}\left[K_0 + (3K_0K_0' - 5K_0)f + \frac{27}{2}\left(K_0K_0'' - 4K_0\right)f^2\right] + (\gamma + 1 - q)\gamma\rho\Delta U_{\mathrm{vib}} - \gamma^2\rho\Delta(C_{\mathrm{V}}T) \qquad [24]$$

$$G = (1+2f)^{5/2}\left[G_0 + (3K_0G_0' - 5G_0)f + \left(6K_0G_0' - 24K_0 - 14G_0 + \frac{9}{2}K_0K_0'\right)f^2\right] - \eta_{\mathrm{S}}\rho\Delta U_{\mathrm{vib}} \qquad [25]$$

where f is the Eulerian strain measure

$$f = \frac{1}{2}\left[\left(\frac{V}{V_0}\right)^{-2/3} - 1\right] \qquad [26]$$

and subscript 0 indicates the value of a quantity at the reference state (e.g., ambient conditions), primes indicate pressure derivatives, and Δ indicates the difference between the temperature of interest and the temperature of the reference state. The quantity η_{S} takes on positive values near unity for mantle phases and derives from the shear part of the fourth-rank tensor formed from the strain derivative of the tensorial generalization of γ, which we have assumed to be isotropic. Taking typical values of γ and q (1 and 2, respectively), the temperature-dependent terms show that both moduli decrease with increasing temperature at constant volume. The decrease with increasing temperature at constant pressure is greater than that at constant volume according to

$$\left(\frac{\partial M}{\partial T}\right)_{\mathrm{P}} = \left(\frac{\partial M}{\partial T}\right)_{\mathrm{V}} - \rho C_{\mathrm{V}}\gamma M_0' \qquad [27]$$

where M stands for either the bulk or the shear modulus.

Finite-strain theory suggests systematic relationships between the values of the pressure derivatives of the elastic constants and the moduli themselves (Karki et al., 2001). It has been known for some time that the Eulerian finite strain theory owes its success at least in part to that fact that it rapidly converges to experimentally measured equations of state with increasingly higher orders of the finite strain. In fact, for many materials, the lowest-order terms suffice. The term linear in f in the normalized equation of state vanishes when $K_0' = 4$, a value that is typical of mantle phases and many other materials as well. We may take the same approach in the case of eqns [24] and [25] and ask what relationships are implied by the vanishing of the term linear in f within the square brackets. In the case of the shear modulus, this yields a relationship between the pressure derivative of G and the ratio of shear modulus to bulk modulus, which is satisfied approximately for mantle phases (Stixrude and Lithgow-Bertelloni, 2005a). The temperature

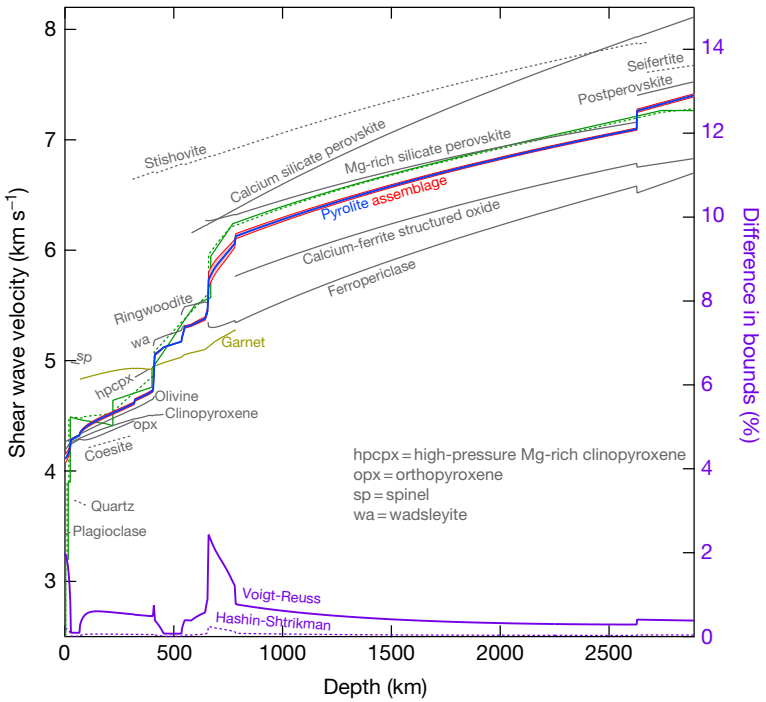

Figure 8 Velocities of mantle phases (gray lines), a pyrolite assemblage (blue with red envelope indicating Voigt–Reuss bounds), and the difference between Voigt–Reuss bounds (solid purple line) and Hashin–Shtrikman bounds (dashed purple line) on the velocity of the assemblage (purple, right-hand axis) along a self-consistently computed 1600 K isentrope. The velocity of phases is plotted over their pressure range of stability. Silica phases are not stable in pyrolite and are shown for comparison. Green lines are radial seismological models: (solid) PREM (Dziewonski and Anderson, 1981) (dashed) AK135 (Kennett and Engdahl, 1991). Computed with HeFESTo (Stixrude and Lithgow-Bertelloni, 2011). Reproduced from Stixrude L and Lithgow-Bertelloni C (2012) Geophysics of chemical heterogeneity in the mantle. *Annual Review of Earth and Planetary Sciences* 40: 569–595.

derivative of the shear modulus scales with the value of the shear modulus itself (Stixrude and Lithgow-Bertelloni, 2005a).

We can relate the elastic moduli of mantle phases to those found seismologically via a compilation of experimental and theoretical results for the parameters appearing in eqns [24] and [25] (**Figure 8**). Comparison with seismological observations tends to support the standard model of a homogeneous peridotite composition for the entire mantle. Peridotite is a rock primarily composed of the mineral olivine. Model mantle compositions, based on comparison with seismology, the genesis of magmas, and the analysis of mantle xenoliths, typically contain 50–60% olivine and lesser amounts of orthopyroxene, clinopyroxene, and garnet. Peridotites produce a series of phase transformations with increasing depth: the velocity of the upper mantle is spanned by that of olivine, orthopyroxene, clinopyroxene, and garnet; in the shallow transition zone (410–520 km), by clinopyroxene, majorite, and wadsleyite; and in the deep transition zone (500–660 km), by Ca-perovskite, ringwoodite, and majorite. Velocities in the lower mantle are spanned by those of Mg-perovskite, magnesiowüstite, and Ca-perovskite. In the upper mantle and transition zone, we find that the change in shear-wave velocity due to phase transformations exceeds the influence of pressure on the velocity of any one phase. This suggests the essential role that phase transformations play in producing the anomalous velocity gradient of the transition zone and emphasizes the importance of going beyond the elasticity of individual minerals in understanding mantle structure, as we will discuss further in the next section.

One of the most remarkable patterns in the temperature and compositional derivatives of the elastic moduli, aside from the large influence of compression discussed earlier, is the large difference between garnet–majorite and other phases (**Figure 9**). The compositional derivative for garnet and majorite (and clinopyroxene) is only a third those of olivine and orthopyroxene, while the temperature derivatives of garnet and majorite are approximately half those of olivine and orthopyroxene. The contrast in compositional derivatives can be traced directly to the shear modulus of Mg and Fe end-members of the phases: while the shear modulus of fayalite is 40% less than that of forsterite, that of almandine is actually slightly greater than that of pyrope, partially offsetting the effect of the greater density of almandine on V_S. The contrast in temperature derivatives can be related to experimental measurements of dG/dT of the dominant species: 8 and 9 MPa K^{-1} for pyrope and majorite, respectively, compared to 15 MPa K^{-1} for forsterite. One consequence of the unusual properties of garnet is that the influence of temperature and iron content is sensitive to bulk composition. Specifically, more garnet-rich compositions, such as basalt, are less sensitive to variations in temperature or iron content than garnet-poor bulk compositions such as harzburgite (Speziale et al., 2005). (Basalt is a rock primarily composed of pyroxene and plagioclase feldspar that makes up most of the oceanic crust and is produced by partial melting of the mantle. Harzburgite is a rock that is richer in olivine than the average mantle and is thought to be the residuum of partial melting of the mantle.)

1.26.3 Rock Elasticity

1.26.3.1 Overview

Knowledge of mineral elasticity is necessary for estimating the elastic properties of a rock, but it is not sufficient. There are two primary considerations. The first is that rocks are heterogeneous. In the mantle, this heterogeneity is most pronounced at the grain scale (1–10 mm): every part of the mantle is made of several different mineral phases, each with different elastic properties. The difference in elastic properties between coexisting minerals is generally larger than that between different mantle rock types. The second difficulty is that minerals tend to be preferentially aligned by deformation. The alignment is neither perfect, in which case the elasticity would reduce to that of a single crystal, nor negligible. Indeed, the detection of preferential alignment via the resulting anisotropic propagation of seismic waves is one of our most powerful potential probes of mantle flow.

In principle, one needs to know – in addition to the elastic-constant tensors of the constituent minerals – the location, size, shape, and orientation of each mineral grain in the assemblage. But such a detailed description is neither practical nor useful: a part of the Earth's mantle the size of a typical mantle body wave (100 km) contains on the order of 10^{21} individual mineral grains, assuming 1 cm grains! This is another statement of the spatial aliasing problem described earlier. Model statistical distributions of mineral geometry play an important role, in particular in the analysis of preferred orientation. Idealizations, in which either the preferred orientation or the spatial inhomogeneity, or both, is simplified and permits exact solutions or rigorous bounds, are also important.

Additional complications arise at finite frequency: Dissipative mechanisms exist in aggregates that are not present in single crystals, and these are thought to be important for producing attenuation and dispersion in the mantle, particularly at grain boundaries.

1.26.3.2 Composites Theory

Consider first a homogeneous isotropic medium, corresponding to a glass or a liquid. The elasticity is completely characterized by two elastic constants, which may be taken to be the bulk modulus, K, and shear modulus, G. The longitudinal and shear-wave velocities for all propagation and polarization directions are

$$V_P = \sqrt{\frac{K + 4/3G}{\rho}} \quad V_S = \sqrt{\frac{G}{\rho}} \qquad [28]$$

where ρ is the density and, in the case of a liquid deformed on a timescale long compared with its Maxell relaxation time, $G = 0$.

Consider an inhomogeneous system consisting of N isotropic phases with distinct elastic properties, such that phase α has bulk and shear moduli K^α and G^α and $\alpha = 1,\ldots,N$. Suppose that the only properties of the grain geometry we know are the volume fractions of the phases ϕ^α. The volume fraction is the only feature that is uniquely determined by the usual equilibrium thermodynamics and is thus independent of the history of the sample. The stress and strain tensors are now functions of position:

$$\sigma_{ij}(\mathbf{x}) = c_{ijkl}(\mathbf{x})\varepsilon_{kl}(\mathbf{x}) \qquad [29]$$

$$\varepsilon_{ij}(\mathbf{x}) = s_{ijkl}(\mathbf{x})\sigma_{kl}(\mathbf{x}) \qquad [30]$$

where the compliance tensor is the inverse of the elastic-constant tensor:

$$s_{ijkl} = c^{-1}_{ijkl} \qquad [31]$$

The volume average stress and strain of the rock are assumed related to that in each of the phases by

$$\bar{\sigma}_{ij} = \sum_\alpha \phi^\alpha \bar{\sigma}^\alpha_{ij} \qquad [32]$$

$$\bar{\varepsilon}_{ij} = \sum_\alpha \phi_\alpha \bar{\varepsilon}^\alpha_{ij} \qquad [33]$$

where the bars indicate volume averages. We define the effective elastic moduli of the composite as

$$\bar{\sigma}_{ij} = c^*_{ijkl}\bar{\varepsilon}_{kl} \qquad [34]$$

If we assume that the average stress and strain in each phase are a unique function of the average stress and strain, respectively, of the aggregate, then it is possible to show that the values of c^* are bounded such that

$$M^*_R = \left(\sum_\alpha \frac{\phi^\alpha}{M^\alpha}\right)^{-1} < M^* < \sum_\alpha \phi^\alpha M^\alpha = M^*_V \qquad [35]$$

where M refers to either K or G and the bounds M^*_R and M^*_V correspond, respectively, to the assumption that the stress (Reuss bound) and strain (Voigt bound) are homogeneous throughout the composite (Hill, 1963; Watt et al., 1976). Except in special geometries, neither of these approximations is correct: the assumption of constant stress requires the opening of gaps between grains, while the assumption of constant strain violates mechanical equilibrium. Indeed, the assumptions embedded in eqns [32] and [33] are in general not justifiable, and one of the complications of composites theory is that the stress tensor can no longer be treated as symmetric (e.g., Juanzemis, 1967).

Ignoring these complications, the Voigt and Reuss bounds limit the possible degree of anisotropy due to inhomogeneous arrangement of phases. This type of anisotropy is sometimes referred to as shape-preferred orientation. Plane layering is the classic example for which Voigt and Reuss bounds can be realized (Backus, 1962). The P-wave velocity for waves propagating normal to the layers is $\rho V_P^2 = K_R + 4/3G_R$, while that for propagation parallel to the layers is $\rho V_P^2 = K_V + 4/3G_V$. Thus, heterogeneity produces anisotropy. This relationship has been examined on the atomic level as well. There are several crystal structures in which layers of more compressible units, for example, Mg coordination polyhedrons, alternate with layers of stiffer units such as Si polyhedrons. Such alternation leads to the large anisotropy of the olivine structure (Hazen et al., 1996; Wentzcovitch and Stixrude, 1997).

For illustration, we compare the Voigt and Reuss bounds of a typical mantle lithology (peridotite) in **Figure 8**. The bounds are wide in the shallow mantle due to the extremely low velocity of plagioclase and in the vicinity of the 660 km discontinuity due to the much higher velocity of perovskite than garnet, whereas they are nearly coincident in the shallow transition zone where wadsleyite and garnet have similar velocities. In the lower mantle, the bounds differ by less than 2% and by less than 1% at the core–mantle boundary. These results suggest that shape-preferred orientation in subsolidus peridotites is unlikely to be the source of anisotropy in the D" layer at the base of the mantle, as has previously been proposed on the basis of the contrast in elastic properties between perovskite and periclase (Karato, 1998).

It is not possible to estimate more precisely the value of the effective elastic moduli without further information. It is common in the literature to quote the so-called Voigt–Reuss–Hill mean, which is simply the arithmetic mean of the Voigt and Reuss bounds (Hill, 1952). This value is not rigorously justified as a best estimate of the actual effective moduli.

With further assumptions about the distribution of the phases, it is possible to derive narrower bounds. The Hashin–Shtrikman analysis (Hashin and Shtrikman, 1963) assumes that the distribution of phases is statistically random and that the elastic properties of the aggregate are given as a solution to a variational problem. So, for example, regular arrangements such as layering are excluded. The Hashin–Shtrikman bounds, given in compact form by Berryman (1995), are narrower than the Voigt–Reuss bounds in most cases, including for the mantle (**Figure 8**). Watt et al. (1976) recommend that the Hashin–Shtrikman bounds should generally be used in reporting the elastic properties of multiphase materials, rather than the Voigt–Reuss bounds, or the VRH average. However, this may be misleading because the Hashin–Shtrikman bounds are based on a limiting assumption excluding geometries that are important in some parts of the Earth (e.g., layering).

In certain cases, the Voigt–Reuss and Hashin–Shtrikman bounds are too wide to yield useful estimates. This can occur when the moduli of the constituent phases differ significantly, as in the case of a porous solid or a partial melt. In such cases, the analysis of specific geometries may be useful. Typically, one assumes that one phase is the host (i.e., the solid rock) and the other is treated as an inclusion (air, water, or melt). Results for specific inclusion shapes have been derived, including spheres, needles, disks, and penny-shaped cracks (Berryman, 1995). For a given volume fraction of inclusions, the effective moduli are most similar to those of the host for spherical inclusions, whereas large-aspect-ratio disks or cracks have the largest influence on the shear modulus (**Figure 10**) (Williams and Garnero, 1996). It should be noted that very little is known concerning the actual form of melt inclusions in partial melts within the mantle. The relevant controlling parameters are many; include the pressure, temperature, bulk composition, and deformation history; and may be influenced by nonequilibrium effects (Bruhn et al., 2000; Hier-Majumder and Abbott, 2010).

An additional ambiguity in the computation of the effective elastic moduli of isotropic composites arises from the intrinsic anisotropy of crystals. Even in the case of a monophase aggregate, the effective elastic moduli are inherently uncertain unless the texture has been completely specified (Watt et al., 1976). Hill (1952) showed that rigorous bounds correspond to the

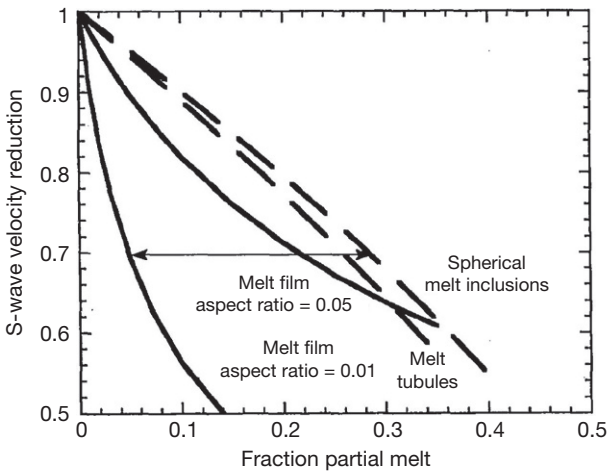

Figure 10 Ratio of the S-wave velocity of melt-bearing mantle to that of solid mantle for varying melt fractions and melt geometries. The arrow corresponds to the variation in melt fraction implied by the inferred P-wave velocity depression of 10% in the ultralow-velocity zone at the base of the mantle. Reproduced from Williams Q and Garnero EJ (1996) Seismic evidence for partial melt at the base of Earth's mantle. *Science* 273: 1528–1530.

assumption of, respectively, homogeneous strain and homogeneous stress. The Voigt (homogeneous strain) bounds are

$$K_V^* = \frac{1}{3}(A + 2B) \quad [36]$$

$$G_V^* = \frac{1}{5}(A - B + 3C) \quad [37]$$

where A, B, and C, are, respectively, the mean diagonal, off-diagonal, and shear elastic constants

$$\begin{aligned} A &= \frac{1}{3}(c_{11} + c_{22} + c_{33}) \\ B &= \frac{1}{3}(c_{12} + c_{13} + c_{23}) \\ C &= \frac{1}{3}(c_{44} + c_{55} + c_{66}) \end{aligned} \quad [38]$$

And the Reuss (homogeneous stress) bounds are

$$K_R^* = \frac{1}{3(a + 2b)} \quad [39]$$

$$G_R^* = \frac{5}{4a - 4b + 3c} \quad [40]$$

where a, b, and c are similar to A, B, and C but with the components of the compliance tensor replacing those of the elastic-constant tensor. The Hashin–Shtrikman bounds for the monophase aggregate are narrower (Hashin and Shtrikman, 1962). Expressions have been derived for cubic, tetragonal, orthorhombic, hexagonal, trigonal, and monoclinic Bravais lattices (Watt, 1988, and references therein). The difference between Voigt and Reuss bounds for the shear-wave velocity of olivine at ambient conditions is 2%. The difference tends to increase with increasing single-crystal anisotropy; in fact, the difference between Voigt and Reuss bounds has been proposed as the basis for a universal anisotropy index (Ranganathan and Ostoja-Starzewski, 2008). For materials with very large anisotropy, such as periclase at the core–mantle boundary (azimuthal shear anisotropy = 60%), Voigt and Reuss bounds on the shear modulus differ by 30% and the Hashin–Shtrikman bounds differ by 5% (Karki et al., 2001). Spinel is an example of a mineral that is extremely anisotropic at ambient conditions and for which bounds are wide (Yoneda, 1990).

Preferred orientation (preferential crystallographic alignment) of the constituent grains results in macroscopic anisotropy detectable by seismic waves. The preferred orientation is characterized by the orientation distribution function:

$$f(\mathbf{g})\mathrm{d}\mathbf{g} = \frac{\mathrm{d}V_\mathbf{g}}{V} \quad [41]$$

where $\mathbf{g}$ is the rotation matrix that relates the crystallographic axes to the spatial or laboratory reference frame and $\mathrm{d}V_\mathbf{g}/V$ is the volume fraction of crystals with orientation lying within the range $\mathrm{d}\mathbf{g}$. The effective elastic moduli of the aggregate may then be estimated by (Bunge et al., 2000)

$$c_{ijkl}^* = \int_g g_{im} g_{jn} g_{ko} g_{lp} c_{mnop} f(\mathbf{g})\,\mathrm{d}\mathbf{g} \quad [42]$$

where the effective elastic moduli are referred to the laboratory frame and the elastic-constant tensor in the integrand is referred to the crystallographic frame. This expression yields the Voigt bound on the effective elastic moduli; the Reuss bound involves the compliances. Two simple cases of orientation distribution functions are of special interest (Stixrude, 1998). If the texture is perfect, that is, all crystals identically aligned, then the effective elastic-constant tensor is identical to that of the single crystal rotated into the laboratory frame. Such a texture might be considered the asymptotic limit of lattice-preferred orientation produced by mantle flow. A transversely anisotropic aggregate is produced if deformation is dominated by an easy-glide plane. In this case, the effective elastic-constant tensor has hexagonal symmetry with the symmetry axis normal to the glide plane.

1.26.3.3 Attenuation and Dispersion

When deformed by small stresses over short timescales, the mantle behaves nearly elastically, propagating shear waves, whereas at long timescales, it behaves like a fluid, deforming viscously in mantle convection. (Though not relevant to the immediate discussion, rock also behaves as a fluid under the short but high-amplitude stresses of impact-induced shock.) The boundary between these two types of behavior is characterized by the Maxwell relaxation time:

$$\tau_M = \frac{\eta}{G} \quad [43]$$

where η is the viscosity. For the upper mantle, $\tau_M \sim 1000$ years and determined from glacial rebound.

At seismic periods, deformation is also not perfectly elastic. The relative amount of elastic energy lost per cycle, $\mathrm{d}E/E$, defines the quality factor Q, the inverse of which is referred to as the internal friction or attenuation:

$$Q^{-1} = \frac{\mathrm{d}E}{E} \quad [44]$$

Attenuation entails dispersion: the acoustic-wave velocity depends on the wavelength or frequency of the probe (Figure 11) (Jackson, 2000). This results from causality, the requirement that the

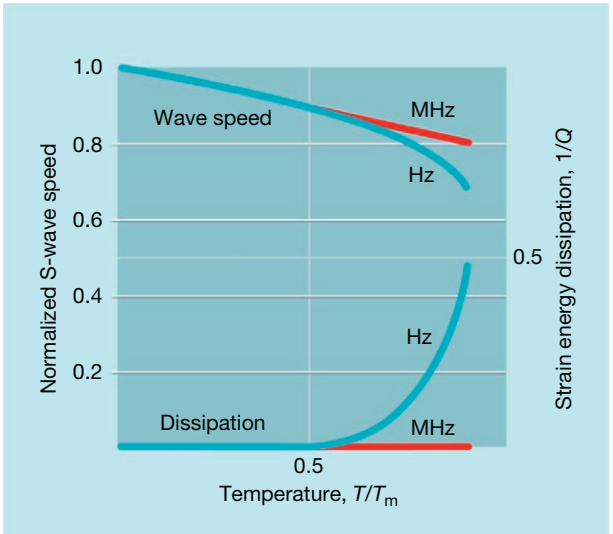

Figure 11 Schematic representation of the variation of acoustic-wave velocity (upper curves) and attenuation (Q^{-1}) (lower curves) with temperature at high frequencies (red) and lower frequencies within the seismic band (blue). Reproduced from Jackson I (2000) Geophysics – Taking the Earth's temperature. *Nature* 406: 470–471.

mechanical energy of the wave cannot propagate faster than the signal velocity, as encapsulated by the fact that the frequency-dependent elastic modulus and attenuation are not independent: they are Hilbert transform-related real and imaginary components of the complex modulus (eqn [47]) and therefore satisfy integral conditions (Kramers–Kronig relations) (Bracewell, 1999). This kind of dispersion – which involves nonequilibrium processes, with mechanical energy converted to heat – is distinct from the dispersion we encountered in the context of lattice dynamics of perfect crystals, which is an equilibrium phenomenon arising from the atomic nature of matter.

Simple models are useful for thinking about attenuation and dispersion, even when they do not correspond to geophysically relevant materials. The Maxwell model is the simplest, consisting of an elastic spring and a dashpot in series. The Voigt model has these two elements in parallel. At short periods, both of these simple models produce elastic behavior governed by the spring. At long periods, the behavior is very different. Whereas the Maxwell model produces a purely viscous, unrecoverable response, governed by the dashpot, the Voigt model shows anelastic behavior: time-dependent but fully recoverable. The so-called Kelvin or standard linear solid consists of a Voigt model in series with a spring. The simplest model that shows the full range of response, elastic, anelastic, and viscous, is the Burgers model, which can be thought of as a Maxwell solid and a Voigt solid in series. See, for example, Cooper (2002) for a recent discussion of these models.

These simple models make an important point. Viscous flow, which governs mantle convection, and anelastic deformation, which causes attenuation and dispersion in the seismic band, are considered as separate dashpots. While the connection to real materials is not obvious, it is likely that viscosity and attenuation are governed by separate microscopic deformation mechanisms if for no other reason than that the strain rates and total strains are so vastly different. Experimental measurements of viscosity, which are more numerous than measurements of seismic attenuation at relevant mantle conditions, are not necessarily a reliable guide to the dependence of attenuation on pressure, temperature, or composition.

Consider the response of these models to periodic loading

$$\sigma = \sigma_0 e^{i\omega t} \qquad [45]$$

which produces the strain response

$$\varepsilon = \varepsilon_0 e^{i\omega t+\delta} \qquad [46]$$

In most experiments, the attenuation is actually measured by the phase lag δ. The elastic modulus is complex and frequency-dependent:

$$M(\omega) = M_R + iM_I \qquad [47]$$

and the attenuation can also be written as the ratio of imaginary to real parts $Q^{-1} = M_I/M_R$. The acoustic-wave velocity is

$$V = \sqrt{\frac{M}{\rho}} \qquad [48]$$

where ρ is the density.

The simple models described all predict attenuation that depends strongly on frequency (**Figure 12**). For the Maxwell solid $Q^{-1} = 1/\omega\tau$, and for the Voigt solid, $Q^{-1} = \omega\tau$, where τ is the characteristic relaxation time. The standard linear solid shows Maxwell-like and Voigt-like behavior in the limit of zero and infinite frequency, respectively, with a peak attenuation centered at $\omega\tau = 1$:

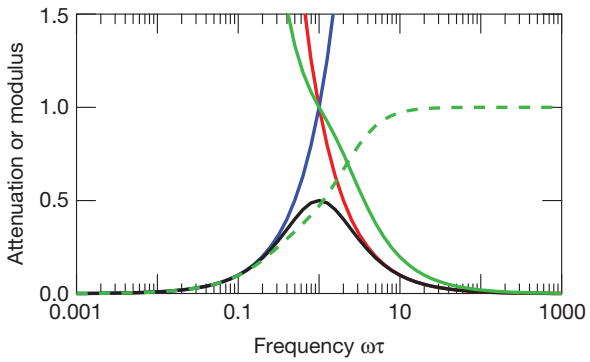

Figure 12 Frequency dependence of the attenuation (solid curves) and modulus (dashed curve for the Burgers model) for simple mechanical models: Maxwell (red), Voigt (blue), Kelvin (black), and Burgers (green). Reproduced from Stixrude L and Lithgow-Bertelloni C (2012) Geophysics of chemical heterogeneity in the mantle. *Annual Review of Earth and Planetary Sciences* 40: 569–595.

$$Q^{-1} = \frac{\omega\tau}{1+(\omega\tau)^2} \qquad [49]$$

and the velocity dispersion is

$$V(\omega) = V(0)\left(1 + Q^{-1}_{\max}\frac{(\omega\tau)^2}{1+(\omega\tau)^2}\right) \qquad [50]$$

For the Burgers model

$$Q^{-1} = \frac{1+2\omega^2\tau^2}{2\omega\tau+\omega^3\tau^3} \qquad [51]$$

there is a Maxwell-like decrease of attenuation with increasing frequency, interrupted by a region near $\omega\tau = 1$ where the dependence on frequency is much reduced. Depending on the details of how the Burgers model is parameterized, this shoulder may become a small peak.

Much of the literature on microscopic mechanisms of attenuation in solids has focused on those materials that show clear peaks in the attenuation spectrum. The dependence of the peak amplitude and frequency on temperature and material characteristics is essential for identifying the mechanism(s) responsible. Among the mechanisms that have been identified in this way are the migration of defects, the exchange of substituents in solid solution, dislocation motion, grain-boundary relaxation, and thermal currents (Jackson and Anderson, 1970; Nowick and Berry, 1972). Because so many mechanisms can contribute to the attenuation, it is often necessary to specially prepare the sample to have, for example, high purity or uniform grain size, in order to produce a spectrum with a single clear peak. Many silicate liquids show attenuation that is well described by a single characteristic relaxation time (Rivers and Carmichael, 1987).

Perhaps, the most important result from the studies of mantle-like materials is the absence of attenuation peaks (Jackson et al., 2002). Attenuation is found to vary slowly and monotonically with frequency over a broad spectrum. The reason for this behavior is not clear. It is possible that there exists a broad and nearly continuous spectrum of relaxation times. The behavior is similar to the so-called high-temperature background found in many materials (Nowick and Berry, 1972). Even those materials that show distinct peaks at low temperature may exhibit featureless attenuation spectra at high temperature.

In the case of attenuation dominated by elastically accommodated grain-boundary sliding, the featureless, nearly flat attenuation spectrum may be rationalized as follows (Jackson et al., 2002). The characteristic relaxation time is

$$\tau_{gb} = \gamma \frac{\eta_{gb} d}{G\delta} \qquad [52]$$

where d is the grain size, δ is the width of the grain-boundary region, γ (not the Grüneisen parameter, here) is of order 1, and η_{gb} is a grain-boundary viscosity (much less than the viscosity of the bulk). A spectrum of relaxation times might be produced by a distribution of grain sizes, grain-boundary widths, and grain-boundary viscosities. In particular, the effective grain-boundary viscosity could exhibit a wide range because of the variable presence of grain-boundary irregularities or impurities that would tend to inhibit sliding.

The following empirical expression represents the data of Jackson et al. (2002) within the seismic frequency band (~1–100 s periods) (**Figure 13**):

$$Q^{-1}(P,T,\omega) = Ad^{-m}\omega^{-\alpha}\exp\left(-\alpha\frac{E^* + PV^*}{RT}\right) \qquad [53]$$

$$V(P,T,\omega) = V(P,T,\infty)\left[1 - \frac{1}{2}\cot\left(\frac{\alpha\pi}{2}\right)Q^{-1}(P,T,\omega)\right] \qquad [54]$$

where ω is the frequency, d is the grain size, $m = 0.28$ is the grain size exponent, $\alpha = 0.26$ is the frequency exponent, $E^* = 430$ kJ mol^{-1} is the activation energy, V^* is the activation volume, and R is the gas constant. For the experimental value of α, the factor multiplying Q^{-1} in eqn [53] has the value 1.16. The activation volume is currently unconstrained, which means that the influence of pressure on attenuation is highly uncertain. The relationship between attenuation and dispersion is made explicit by eqn [54].

The experimental results can be compared with attenuation spectra proposed for the Earth. The absorption band model (Anderson and Given, 1982) consists of a broad frequency range over which Q^{-1} depends weakly on frequency, bounded by narrower low- and high-frequency ranges where Q^{-1} decreases to zero. The intermediate frequency range of this model, the absorption band, agrees well with experimental results. The estimates of the value of alpha based on seismological observations are consistent with those found experimentally at similar frequencies. But experimental support for the boundaries of the absorption band is lacking. At long periods, experiments show that the attenuation will continue to increase with increasing period and at a higher rate, with $\alpha = 1$ (Gribb and Cooper, 1998; Jackson et al., 2002). At the high-frequency end, there is no indication of a sharp transition

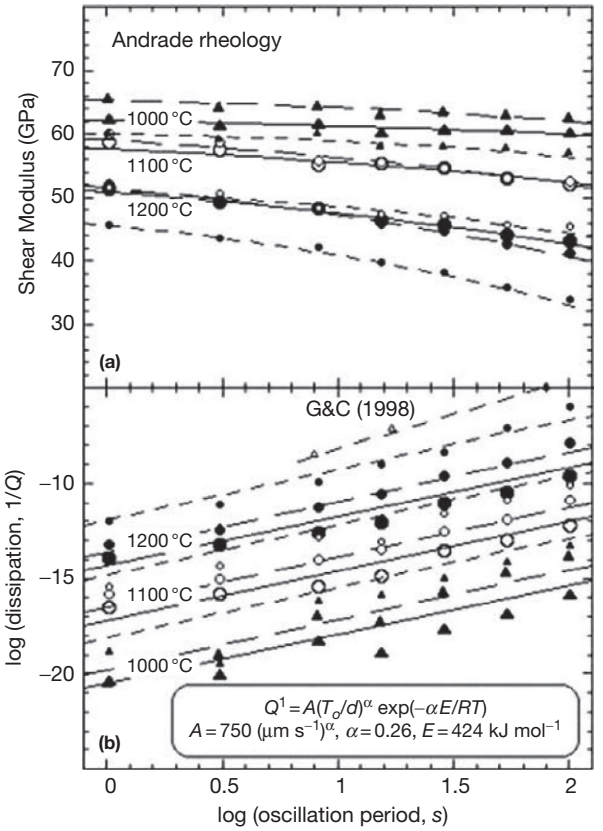

Figure 13 Grain size sensitivity of the high-temperature mechanical behavior of olivine polycrystals. Data for specimens 6261, 6365, and 6381 of average grain sizes 23.4, 12.4, and 2.9 mm are denoted by the large, medium, and small plotting symbols and by the solid, long-dashed, and short-dashed curves, respectively. Solid circles, open circles, and solid triangles denote data for 1200, 1100, and 1000 °C, respectively. (a) Shear modulus. Curves labeled with temperature indicate the modulus dispersion associated with Andrade models fitted simultaneously to $G(T_o)$ and $Q^{-1}(T_o)$, where $T_o = 2\pi/\omega$ is the oscillation period (cf. eqns [53] and [54]). (b) The log (dissipation, Q^{-1}). Lines represent the preferred fit (eqns [7] and [8]) to the entire 1000–1300 °C, 1–100 s data set for all four specimens, except for the uppermost line representing the results of Gribb and Cooper (1998) for a resynthesized dunite of 2.8 mm grain size at 1200 °C. Reproduced from Jackson I, Gerald JDF, Faul UH, et al. (2002) Grain-size-sensitive seismic wave attenuation in polycrystalline olivine. *Journal of Geophysical Research-Solid Earth* 107: 2360.

requiring a larger value of α. In fact, there is an indication in the data that the attenuation becomes less sensitive to frequency at high frequency (Cooper, 2002).

The influence of partial melt is generally to increase the attenuation (Faul et al., 2004; Jackson et al., 2004). The frequency dependence is also affected by partial melt. A broad absorption peak is superimposed on a high-temperature background. The origin of this peak appears not to be the melt squirt mechanism that has been widely discussed, but elastically accommodated grain-boundary sliding enhanced by partial melt. For probable mantle-grain sizes and attenuation in the seismic band, Q is nearly independent of frequency for 1% partial melt.

The influence of crystallographically bound hydrogen on the attenuation is currently not well constrained, although it is

known that viscosity decreases with increasing hydrogen concentration (Mei and Kohlstedt, 2000a,b).

The bulk attenuation – that is, the time dependence of volume compression due to a change in hydrostatic pressure – is much smaller than shear attenuation. Seismological observations require a small but finite value of the bulk attenuation in the Earth, the locus of which is difficult to resolve uniquely (Durek and Ekstrom, 1995). In the limit that bulk attenuation vanishes, the attenuation of longitudinal and shear waves is related by

$$Q_P^{-1} = \frac{4}{3}\left(\frac{V_S}{V_P}\right)^2 Q_S^{-1} \qquad [55]$$

Experimental measurements and theoretical analyses of possible mechanisms also find that bulk attenuation is much smaller than shear attenuation: proposed mechanisms for bulk attenuation involve the elastic heterogeneity of polyphase assemblages, coupling to the kinetics of first-order phase transformations, and compositional fluctuations in the liquid outer core (Anderson, 1980; Heinz et al., 1982; Li and Weidner, 2008; Ricard et al., 2009).

1.26.4 Seismological Elasticity and Anelasticity

1.26.4.1 Scaling

When the scale length of heterogeneity is comparable to the seismic wavelength, there are two additional considerations. The first is dispersion due to structure. This is seen in observations of surface waves, the velocity of which depends on frequency. This frequency dependence is mostly due to the fact that larger wavelengths sample greater depths where the intrinsic acoustic velocity is greater.

Random heterogeneity can produce scattering of seismic waves (Frankel and Clayton, 1986). Consider a random medium with average velocity, v, characterized by heterogeneity of length scale a and velocity perturbation, d, and probed by acoustic waves with wavelength λ. On average, the first-arriving waves tend to select paths that preferentially sample the high-velocity heterogeneities; in this sense, the medium appears to have a wave velocity slightly greater than v. In addition, the velocity depends on wavelength, that is, heterogeneity causes dispersion. The direct wave is attenuated, as energy is redirected due to scattering, but this is essentially different from the intrinsic attenuation discussed earlier for which mechanical energy is dissipated by being converted to heat. The difficulty, however, is that scattering due to heterogeneity has many of the same characteristics as intrinsic attenuation and dispersion of seismic waves, so the two causes of seismic-wave attenuation as a function of distance along the wave path – scattering versus dissipation – are difficult if not impossible to disentangle. This means that any interpretation of attenuation in terms of the strong temperature dependence expected from intrinsic (dissipative) mechanisms, for example, needs to be treated with caution.

What is the scale of heterogeneity in the mantle? The magnitude of the heterogeneity is largest at the grain scale, with differences in shear-wave velocity between coexisting minerals being 10–30% throughout most of the outer mantle (except for the shallow transition zone) as well as near the core–mantle boundary (Figure 14). The ratio of the grain size typically observed in mantle xenoliths (1–10 mm) to teleseismic wavelengths is $d/\lambda \sim 10^{-7} \ll 1$ characteristic of Rayleigh scattering. In this long-wavelength limit, the apparent attenuation falls with increasing wavelength like $(d/\lambda)^3$ and is probably negligible as long as the heterogeneity is weak (say less than 1–10%). The grain-scale heterogeneity indicated in Figure 14 can plausibly be accommodated within the Rayleigh-scattering model, but it is less likely that the stronger heterogeneity associated with partial melt or major compositional variations (e.g., mixtures of core metal and mantle silicates) can also be considered in this weak-scattering limit. Moreover, the grain size of the mantle is still highly uncertain at great depth, particularly below the zone of magma genesis (Ave Lallemant et al., 1980).

Larger-scale heterogeneities, approaching or comparable to seismic wavelengths, are also likely in the mantle (Stixrude and Lithgow-Bertelloni, 2012). At the mid-ocean ridge, basalt and a depleted residuum, harzburgite, are generated, both of which have significantly different physical properties from undifferentiated mantle. The initial scale length of heterogeneity may be taken as the thickness of the oceanic crust (~7 km), which is likely to scatter seismic waves significantly. The magnitude of the velocity difference depends on depth (Figure 15). Basalt is slower than peridotite at shallow depths, reflecting the well-known difference in velocity between crust and mantle. Basalt then becomes much faster near 100 km depth because of the transition to eclogite (plagioclase and pyroxenes forming garnet under pressure) that increases velocities by approximately 10%. Velocity contrasts in the lower mantle are not as well constrained, but appear to be less than 10%. For comparison, one seismological study found that scattering of P-waves could be explained by heterogeneity with scale length 8 km and magnitude 1% uniformly distributed throughout the mantle, but this result may be biased by contamination from heterogeneity at the base of the mantle (Hedlin et al., 1997).

1.26.4.2 Uncertainties

The largest source of uncertainty in constructing isotropic models of radial upper-mantle and transition-zone structure is

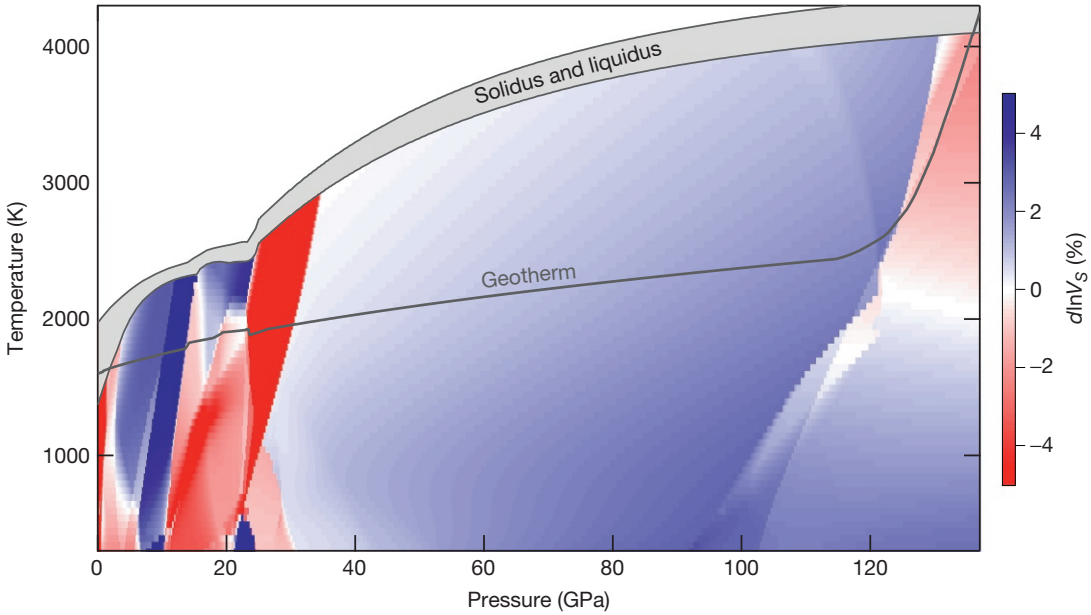

Figure 15 Difference in shear-wave velocity between basalt and harzburgite. The geotherm (thick gray line) and the melting interval (gray envelope) are from Stixrude et al. (2009). Computed with HeFESTo (Stixrude and Lithgow-Bertelloni, 2011). Symbols and units: K, adiabatic bulk modulus (GPa); G, shear modulus (GPa), $X = \mathrm{Fe}/(\mathrm{Mg}+\mathrm{Fe})$; $Y = mj/(py+mj)$; subscript indicates values at zero pressure, and primes indicate pressure derivatives; dK/dT and dG/dT in MPa/K. Italicized entries are unconstrained by experiment. Asterisk indicates values taken from density-functional theoretical calculations. Values in parentheses indicate estimated uncertainties.

the elastic constants of minerals at high pressure and temperature (Table 1). The propagated uncertainty in the elastic shear-wave velocity is approximately 1.3% or 0.06 km s^{-1} (Stixrude and Lithgow-Bertelloni, 2005b). This is somewhat larger than the difference between Voigt and Reuss bounds throughout most of this region and considerably more than the difference between the Hashin–Shtrikman bounds (Figure 8). Uncertainties in computed elastic properties arise mainly because of the need to extrapolate existing measurements taken over limited ranges of pressure and/or temperature to mantle conditions. For a few phases, large discrepancies exist in measured properties that cannot be reconciled at present. An important example is garnet–majorite, for which Brillouin spectroscopy yields a value for $G' = 1.3(2)$ (Sinogeikin and Bass, 2002), while ultrasonic studies yield a much higher value: 1.9 (Liu et al., 2000). We have followed the discussion of Jiang et al. (2004) in favoring the Brillouin value in this case but must emphasize that in this as in other instances of apparent discrepancy, there may be real differences between samples (as yet not recognized or controlled for) and that it is not a question of poor measurements.

These results highlight the importance of measuring elastic properties directly at mantle pressure–temperature conditions. The elastic properties of transition-zone and lower-mantle phases were recently measured at mantle pressure–temperature

conditions for the first time (Higo et al., 2008; Murakami et al., 2012).

Another kind of uncertainty comes from the linkage between velocity dispersion and attenuation, because there is virtually no constraint on the latter at mantle conditions based on laboratory experiments. Simple models, based on the Weertman law (scaling by the ratio of temperature to melting temperature) or a constant activation volume, apparently do not reproduce the qualitative features of seismological radial Q models (Faul and Jackson, 2005). While attenuation has a small effect on the velocity, the lateral variation of velocity in tomographic models is also small, so that intrinsic dispersion is a large part of the 3D structure (Brodholt et al., 2007; Karato, 1993; Matas and Bukowinski, 2007). Progress will come from experimental measurements of Q^{-1} in the seismic band at elevated pressure, an enormous challenge.

In the lower mantle, the reliability with which seismological observations can be interpreted is probably limited by our understanding of the relevant mineral-scale physics. For example, the recently discovered high-spin to low-spin transition (Badro et al., 2003, 2004; Pasternak et al., 1997) appears to have a significant influence on density and elasticity (Mao et al., 2011; Marquardt et al., 2009). While the transition appears to be well understood in ferropericlase, the nature and even existence of a high-spin to low-spin transition in silicate perovskite over the pressure regime of the mantle remains controversial (Hsu et al., 2010; McCammon et al., 2008; Stackhouse et al., 2007). It also remains to be understood how the transition in perovskite depends on compositional variables, such as Al content and ferric iron content (Catalli et al., 2011; Li et al., 2005). Valence transitions induced by pressure, for example, between ferric and ferrous iron also remain poorly understood (Frost et al., 2004), as does the phase diagram of the third most abundant lower-mantle constituent, calcium silicate perovskite. A temperature-induced transition from a low-temperature tetragonal phase to a high-temperature cubic phase has been predicted (Stixrude et al., 1996), and low-temperature structural distortions have been seen experimentally (Shim et al., 2002), but the details remain uncertain. This transition is accompanied by a large elastic anomaly (15% in shear-wave velocity) (Stixrude et al., 2007).

Constructing mineralogical models of anisotropic structure remains a considerable challenge (Nowacki et al., 2013). There has been substantial progress from experiment and theory in our knowledge of the full elastic-constant tensors of major mantle minerals (Karki et al., 2001). We still have a great deal to learn about deformation mechanisms and in particular dominant slip planes at mantle conditions and at relevant strains and strain rates. Experimental results and first-principles calculations now exist for many mantle minerals (Carrez et al., 2007; Cordier, 2002). For lower-mantle minerals, it is important to keep in mind that deformation mechanisms may change profoundly with increasing pressure, as suggested by the change in anisotropy of ferropericlase and magnesium silicate perovskite at high pressure (Karki et al., 1997a,b). Another important uncertainty lies in understanding how polycrystals respond to mantle flow at large finite strains (Blackman et al., 1996; Chastel et al., 1993; Ribe, 1989). This understanding is necessary for estimating the strength of the texture and the resulting magnitude of anisotropy.

Uncertainties related to composite effects are largest in the context of partial melts. The geometry of the melt phase, whether it exists as spheres, needles, or disks, has an enormous effect on the rock shear elasticity. What is required is an understanding of the relevant mineral–melt interface energetics that control this geometry (Hier-Majumder and Abbott, 2010). Melt geometry can be scale-dependent, as demonstrated by experiments in which the melt geometry changes fundamentally on deformation (Bruhn et al., 2000).

1.26.4.3 Implications for Inversions

There are essentially two approaches used for linking seismology and mineral physics, forward and inverse modeling. For the first, a mineralogical model based on an assumed bulk composition and potential temperature is compared with seismological observations (Duffy and Anderson, 1989; Ita and Stixrude, 1992; Stixrude and Lithgow-Bertelloni, 2005b). (For applications to adiabatic temperature profiles in the Earth, the 'potential temperature' refers to the adiabatic temperature at zero pressure.) In practice, mineralogical models are typically compared with seismological models, an approach that is fraught with difficulty because the seismological models are derivative of the data and nonunique. These difficulties are particularly prevalent in the upper mantle, where lateral variations, attenuation, and anisotropy are all large and radial models are prone to mislead.

A promising alternative to forward modeling is to compute the actual seismological observables (e.g., travel times or mode frequencies) directly from the mineralogical model (Cammarano et al., 2009). This permits a much more direct and certain comparison to the structure of the Earth. The uncertainties inherent in the forward model can in principle be assessed and propagated to uncertainties in predicted seismological observables.

An additional benefit of forward mineralogical models is that they might be used as a reference for seismic tomographic inversions. Tomographic models are usually determined as deviations from an assumed radial structure, and the radial model may bias the inversion. For example, in oceanic regions of the upper mantle, tomographic inversions based on preliminary reference earth model (PREM) (Dziewonski and Anderson, 1981) might be biased by the large Lehmann discontinuity in this radial model. PREM and other radial seismic models assume a parametrically simple radial structure. For example, the transition-zone gradient is assumed to be linear, which does not agree with expectations based on the phase transformations that take place in typical mantle lithologies. Advantages of using a mineralogical model would be that all anticipated structure from phase transitions would be included. Moreover, the reference state is one associated with a well-defined, if imprecise, physical meaning in terms of bulk composition and geotherm (Cammarano et al., 2003; Cobden et al., 2009). With ever-improving knowledge of mantle phase equilibriums and physical properties, one may envision substantial improvements in the construction of mineralogical models and our ability to interpret seismological observations in terms of radial and lateral variations in temperature and bulk composition.

An inverse model seeks to invert seismic observations directly for radial and lateral variations in bulk composition and

temperature. In practice, inverse models have been based on the intermediate step of a velocity model. Several studies have inverted radial or 3D velocity and density models for radial and lateral variations in temperature and bulk composition (Deschamps and Trampert, 2003; Goes et al., 2000; Matas et al., 2007; Shapiro and Ritzwoller, 2004; Stixrude et al., 1992; Trampert et al., 2001). Some caution is in order because of the uncertainty in the nonlinear and linked phenomena involved, particularly in the estimate of attenuation. Also important are systematic effects that have not been included in some of these inversions. There are three sources of lateral heterogeneity in the mantle, due to lateral variations of temperature, bulk composition, and phase. The quantities necessary to estimate the influence of phase on lateral structure are reasonably well known in the upper mantle and transition zone: phase equilibriums and physical properties of the minerals involved are experimentally documented and should continue to be included in future efforts (Stixrude and Lithgow-Bertelloni, 2007).

1.26.5 Conclusions and Outlook

The contact between mineral physics and seismology of the Earth's mantle has grown considerably richer and more sophisticated in recent years. Birch's vision of constraining the chemical and thermal state of the mantle on the basis of mineralogical properties and seismic observations is becoming a reality. In addition, mineral physics is beginning to provide the foundation required for inferring the dynamic state of the mantle, and some aspects of its geologic evolution, from the seismological observations.

Progress will come from continued expansion of our knowledge of the elastic properties of mantle minerals at *in situ* conditions of high pressure and high temperature. These data remain the basis for any discussion of mantle structure in terms of radial or lateral variations in temperature or bulk composition. Among recent experimental advances has been a dramatic increase in the pressure and temperature range over which measurements of the shear modulus can be made, to 1 Mbar (2300 km depth) and 2000 K (Murakami et al., 2012). At the same time, first-principles theory continues to make important strides, including in the computation of the elastic constants of important phases over the entire mantle pressure–temperature regime (Oganov et al., 2001; Wentzcovitch et al., 2004; Zhang et al., 2013).

Equally important is a better understanding of recently discovered physics and chemistry, including the postperovskite phase transition, the high-spin to low-spin transition of iron in oxides and silicates, and the possible role of valence state changes of iron at high pressure. Among physical properties that are still poorly understood is the attenuation (or its inverse, the quality factor Q). While recent experiments have laid an important foundation (Gribb and Cooper, 1998; Jackson et al., 2002, 2004; McCarthy et al., 2011), we still have little experimental data bearing on the influence of pressure or water content on attenuation. Also uncertain are the dominant deformation mechanisms in mantle minerals at high pressure and temperature, and these provide an additional link between experimental measurements of the elastic-constant tensor and seismically observed anisotropy. Recent experimental discoveries suggest that more surprises await (Mainprice et al., 2005; Miyagi et al., 2010).

Along with improved knowledge of the physical properties of individual phases will come increasing understanding of aggregate properties and the construction of mineralogical models of the mantle as a whole. An important advance will be closer contact between mineralogical models and seismological observations.

1.27.1 Introduction

The earliest tomography models (e.g., Clayton and Comer, 1983; Dziewonski et al., 1977; Dziewonski, 1984 – reported in Hager and Clayton, 1989; Woodhouse and Dziewonski, 1984) exhibited a large-scale three-dimensional (3-D) structure in Earth's mantle, which was reasonably well correlated to the major surface manifestations of mantle convection, namely, the large-scale nonhydrostatic geoid (Hager et al., 1985) and the large-scale tectonic plate motions (Forte and Peltier, 1987). These early models of mantle heterogeneity thus helped to show that seismic tomography can indeed resolve the lateral variations in mantle structure, which drive the convective flow responsible for the 'drift' of the continents and the large-scale perturbations in Earth's gravitational field.

Steady progress in global seismic tomographic imaging over the past 15 years has yielded models of 3-D mantle structure, which posses significantly improved resolution and reliability (e.g., Antolik et al., 2003; Boschi and Dziewonski, 2000; Ekström and Dziewonski, 1998; Grand, 2002; Kustowski et al., 2008; Li et al., 2008; Masters et al., 2000; Mégnin and Romanowicz, 2000; Ritsema et al., 1999, 2011; Simmons et al., 2010). These improvements are evident in the remarkable accord among the images of large-scale mantle structure

provided by these different models. Such agreement is encouraging, especially when we consider that these models are obtained on the basis of different data sets, different theoretical treatments of seismic wave propagation, and different algorithms for inverting the global seismic data. Helpful reviews of the methods, data sets, and current challenges in global seismic imaging may be found in Dziewonski and Romanowicz (2007) and Thurber and Ritsema (2007).

While the analyses and discussion presented in the preceding text will focus on how seismically inferred 3-D mantle structure may be used to explain geodynamic data and to model mantle flow dynamics, it is important to note that much effort has also been dedicated to the converse approach, namely, to infer 3-D mantle structure from geodynamic data. This inverse approach based on geodynamic constraints began at almost the same time as the earliest global tomography inversions. Hager (1984) proposed a mantle flow model based on estimated density anomalies associated with seismically active subducted slabs and used this model to obtain a good match to very long-wavelength geoid anomalies. Although subsequent studies, for example, by Ricard et al. (1989), attempted a more general inference of mantle heterogeneity using different geodynamic data, the subducted slab geodynamic models developed by Hager (1984) became prevalent. This led, for example, to a study by Forte and Peltier (1989), which constrained the distribution of subducted slab heterogeneity using other geodynamic observables such as tectonic plate motions and core–mantle boundary (CMB) topography. The latter study also attempted to use the geodynamic observables to infer the buoyancy forces associated with mantle plumes under mid-ocean ridges.

Tectonic plate motions and long-wavelength geoid anomalies have proved to be the most important constraints in developing geodynamic models of 3-D mantle heterogeneity in terms of subducted slabs. The geologic history of tectonic plate motions as derived from paleomagnetic data (e.g., Gordon and Jurdy, 1986) has been an especially important ingredient in developing models of both past and present-day subducted slab heterogeneities (e.g., Ricard et al., 1993; Richards and Engebretson, 1992). These models have been very useful for exploring time-dependent dynamics of the mantle (e.g., Lithgow-Bertelloni and Gurnis, 1997; Lithgow-Bertelloni and Richards, 1998). Direct comparisons between the long-wavelength pattern of subducted slab heterogeneity and the corresponding pattern of heterogeneity derived from seismic tomography have shown good correlations at the longest wavelengths (Richards and Engebretson, 1992). When all wavelengths are considered, however, the global correlations between the slab heterogeneity and different tomography models are relatively poor, with correlation coefficients <0.3 throughout the mantle (Figure 7 in Lithgow-Bertelloni and Richards, 1998).

There are various factors that might explain the less than satisfactory agreement between the seismic models of 3-D mantle structure and the reconstructions of mantle heterogeneity in terms of subducted slabs. Firstly, from a purely technical perspective, the evolution of the slab trajectories was not determined in a fluid mechanically consistent manner by numerically solving the advection–diffusion equations. Progress in this direction has been made by Bunge et al. (1998), McNamara and Zhong (2005), and Quéré and Forte (2006) by solving the full set of thermal convection equations with moving tectonic plates as a surface boundary condition. Secondly, the slab models assume that thermally generated heterogeneity dominates in the mantle and this may not be applicable in regions of the mantle with significant compositional heterogeneity (e.g., Forte and Mitrovica, 2001; McNamara and Zhong, 2005). Perhaps the most important deficiency in these efforts to explain mantle heterogeneity in terms of slab subduction alone is that they do not account for the presence and evolution of hot thermal plumes in the mantle, which have been consistently imaged in the global tomography models (e.g., Montelli et al., 2004; Nolet et al., 2006). A recent appraisal of the origin and importance of mantle plumes in convection models that incorporate 3-D mantle structure derived from seismic tomography may be found in Glisovic et al. (2012).

Seismic tomography continues to be the single most important technique for directly inferring the 3-D heterogeneity in the mantle, which is associated with the process of thermal convection. The significant advances in global seismic imaging over the past few years provide the underlying motivation for the detailed discussion of the geodynamic implications, which will be presented in the succeeding text. A recent detailed review by Becker and Boschi (2002) of the currently available tomography models focused on a quantitative analysis of similarities and differences between these models. The work presented in the succeeding text will further extend this previous analysis by carrying out calculations of the mantle flow predicted on the basis of these tomography models and examining in detail the extent to which the tomography-based flow models provide a satisfactory explanation for the main convection-related surface observables.

1.27.2 Geodynamic Observables and Mantle Flow Theory

In the following, the main global geophysical constraints on mantle structure will be presented. These constraints include the free-air gravity anomalies, the dynamic surface and CMB topography, and the tectonic plate motions. The theoretical relationship between these convection-related observables and the internal 3-D structure will be developed in terms of a fluid mechanical model of mantle dynamics.

1.27.2.1 Convection-Related Surface Observations

An understanding of thermal convection in the mantle is necessary for explaining a multitude of geophysical and geologic processes, which we can observe and measure at the surface of the Earth, such as continental drift, earthquakes, mountain building, volcanism, perturbations in Earth's gravitational field, variations in oceanic bathymetry and continental elevation, and long-term changes in global sea-level variations. The principal surface manifestations of mantle convection that have been employed to study the large-scale structure and dynamics of the solid Earth are illustrated schematically in **Figure 1**.

The observational constraints on 3-D mantle structure and dynamics, which will be considered in the succeeding text, are the global free-air gravity anomalies, the dynamic surface and

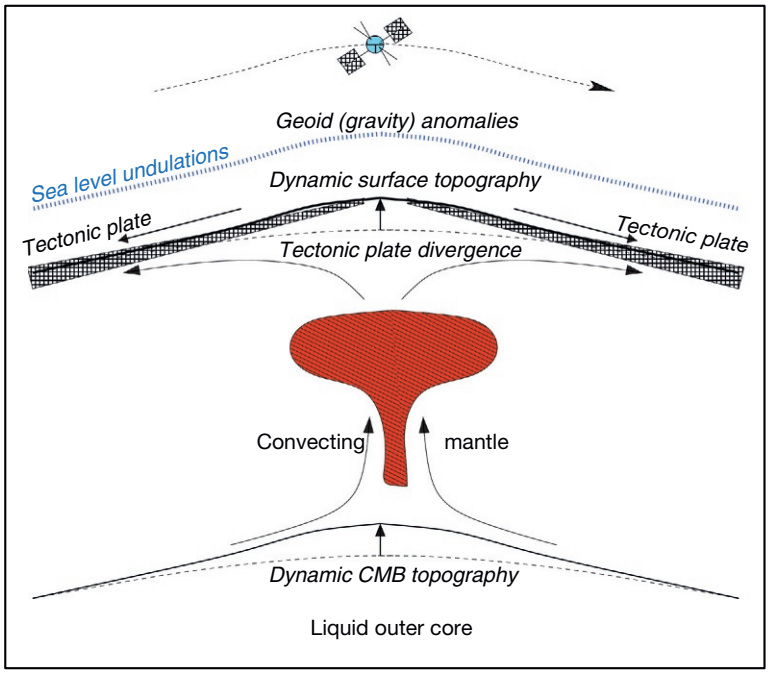

Figure 1 Convection-related surface observations. The most direct manifestations of thermal convection in the mantle (represented schematically by the upwelling plume colored in red) are the surface motions of tectonic plates – which may be summarized by their horizontal divergence field – and the flow-induced topography of the solid surface and the core–mantle boundary (CMB). The boundary undulations and the density anomalies in the mantle (due, e.g., to the hot upwelling plume) give rise to surface gravitational potential perturbations, which may be measured in terms of geoid or gravity anomalies.

CMB topography, and the horizontal divergence of the tectonic plate motions. The Earth's gravitational potential perturbations are usually represented in terms of geoid anomalies; however, as pointed out in Forte et al. (1994), a more detailed and evenly balanced representation (especially at long wavelengths) of the spectral content is provided by the free-air gravity anomalies shown in **Figure 2(a)**.

We will employ the term 'dynamic topography' to mean all contributions to Earth's surface topography, which arise from density anomalies in the convecting mantle – including the lithosphere. Observational constraints on dynamic topography therefore require an accurate model of crustal heterogeneity in order to remove all isostatic crustal contributions to Earth's measured surface topography. The topographic crustal correction, here based on model CRUST2.0 (Bassin et al., 2000), is described in detail by Perry et al. (2003), and the resulting dynamic topography is shown in **Figure 2(b)**.

The tectonic plate velocity field $\mathbf{v}$ may be conveniently summarized in terms of two complimentary scalar fields: the horizontal divergence $\nabla_H \cdot \mathbf{v}$ and the radial vorticity $\hat{\mathbf{r}} \cdot \nabla \times \mathbf{v}$ (Forte and Peltier, 1987). The constraint of plate rigidity imposes a linear dependence between these two scalar fields (Forte and Peltier, 1991), and hence, it suffices that we consider only the plate divergence, shown in **Figure 2(c)**. (A more detailed discussion of the implications of plate rigidity, in terms of allowed plate motions, is also presented in **Section 1.27.2.3.7**.)

The most robust global constraint on deep-mantle density heterogeneity and dynamics (Forte et al., 1995a,b) is currently provided by the dynamic ellipticity of the CMB shown in **Figure 2(d)**. The discrepancy between theoretical predictions of the free core nutation (FCN) period (Wahr, 1981) and the value determined from very long baseline interferometry (Herring et al., 1986) led Gwinn et al. (1986) to conclude that the CMB ellipticity is larger than that implied by theoretical calculations, which assumed a rotating Earth in hydrostatic equilibrium. This inference of an 'excess' ellipticity, in which the nonhydrostatic radius of the CMB at the poles is 400 m less than at the equator, is supported by recent analyses of the FCN period (Mathews et al., 2002).

The most appropriate mathematical basis functions for describing any bounded and continuous function on a spherical surface are the spherical harmonics $Y_\ell^m(\theta, \varphi)$, where position on the spherical surface is defined by colatitude θ and colongitude ϕ. We may therefore expand the geodynamic observables in **Figure 2** in terms of spherical harmonics as follows:

$$f(\theta, \varphi) = \sum_{\ell=0}^{\infty} \sum_{m=-\ell}^{+\ell} f_\ell^m \, Y_\ell^m(\theta, \varphi) \qquad [1]$$

where the function $f(\theta, \phi)$ represents any of the observables (gravity, topography, or plate divergence) and the indices ℓ, m, which characterize each spherical harmonic, are called the *harmonic degree* and *azimuthal order*, respectively. (A useful introduction to spherical harmonic functions may be found in Jackson, 1975.)

The spatial variation of the spherical harmonics is oscillatory in character; it may be characterized in terms of an equivalent horizontal wavelength. On a spherical surface of radius r,

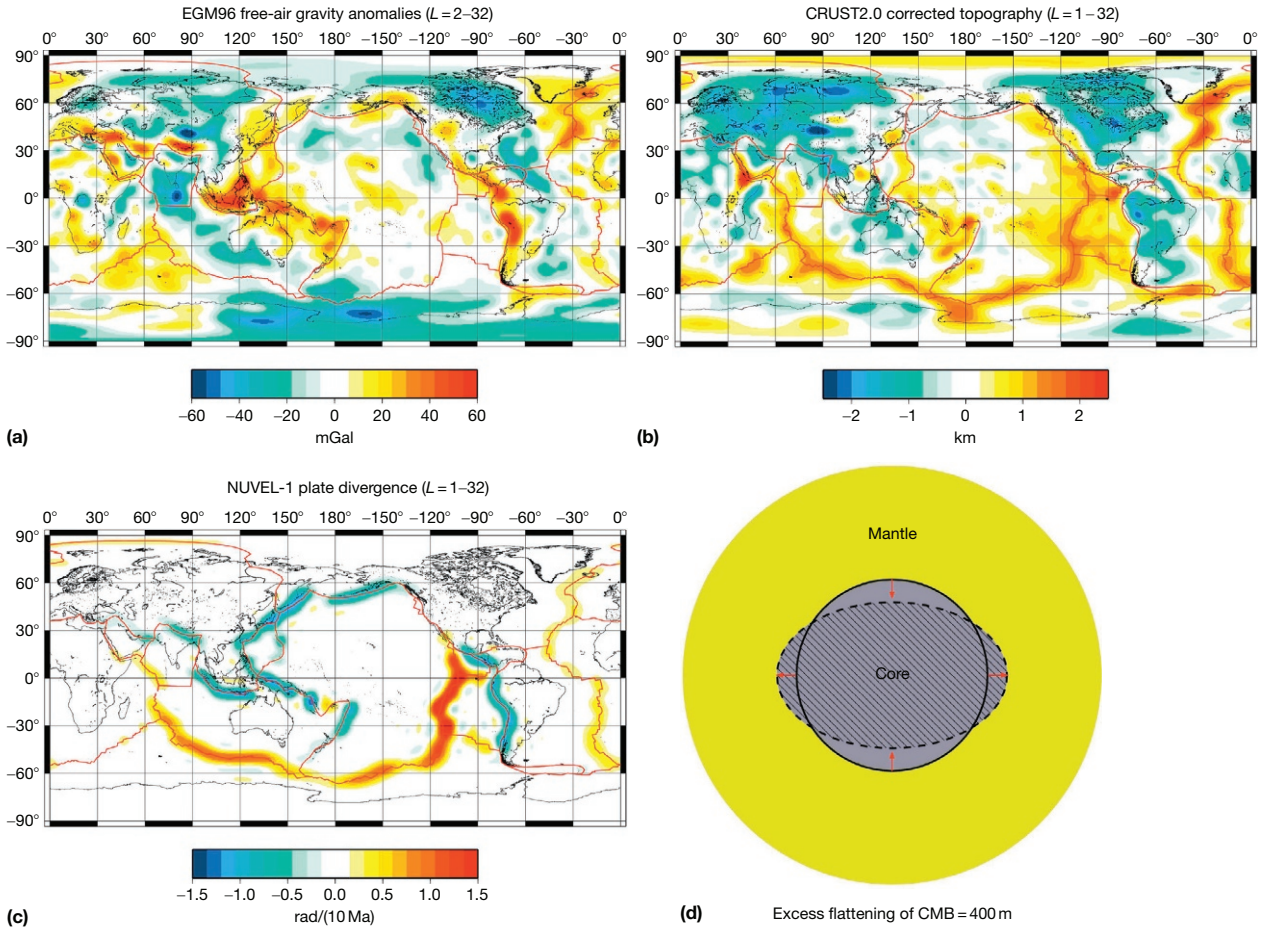

Figure 2 Geodynamic observables. (a) The free-air gravity anomalies derived from the joint geopotential model EGM96 (Lemoine et al., 1998). (b) The dynamic surface topography obtained by removing the topography due to isostatically compensated crustal heterogeneity from Earth's observed topography. The CRUST2.0 (Bassin et al., 2000) crustal heterogeneity model is employed here. (c) The horizontal divergence of the tectonic plate velocities given by the NUVEL-1 model (DeMets et al., 1990). (d) The excess or dynamic CMB ellipticity inferred from core nutation data (Mathews et al., 2002). All fields, with the exception of (d), have been expanded in spherical harmonics up to degree and order 32 (see eqn [1]).

a spherical harmonic $Y_\ell^m(\theta,\varphi)$ has a characteristic wavelength λ_ℓ given by the following expression:

$$\lambda_\ell = \frac{2\pi r}{\sqrt{\ell(\ell+1)}} \approx \frac{2\pi r}{\ell+\frac{1}{2}}, \text{valid for } \ell \gg 1 \qquad [2]$$

In practice, the infinite sum over degree ℓ in eqn [1] is truncated at some finite value ℓ_{max} and for the fields in Figure 2 it is $\ell_{max}=32$. At the Earth's surface ($r=6368$ km), this is equivalent to a minimum horizontal length scale (or half wavelength) of about 600 km.

Spherical harmonic representations of surface fields can be used to quantify their spectral content in terms of an amplitude spectrum. The amplitude spectrum measures the mean (globally averaged) amplitude of a field at a particular wavelength λ_ℓ [2], and it is defined in terms of a 'degree variance' σ_ℓ as follows:

$$\sigma_\ell = \sqrt{\sum_{m=-\ell}^{+\ell} f_\ell^{m^*} f_\ell^m} \qquad [3]$$

in which f_ℓ^m are the spherical harmonic coefficients of the surface field (see expression [1]) and * denotes complex conjugation.

A spectral description of the spatial correlation between two fields, as a function of harmonic degree or wavelength, is quantified in terms of 'degree correlation' r_ℓ, defined as follows:

$$r_\ell = \frac{\sum_{m=-\ell}^{+\ell} f_{1\ell}^{m*} f_{2\ell}^m}{\sqrt{\sum_{m=-\ell}^{+\ell} f_{1\ell}^{m*} f_{1\ell}^m}\sqrt{\sum_{m=-\ell}^{+\ell} f_{2\ell}^{m^*} f_{2\ell}^m}} \qquad [4]$$

in which $f_{1\ell}^m$ and $f_{2\ell}^m$ are the spherical harmonic coefficients of the two fields.

Degree variances and correlations are very useful spectral characterizations of the amplitude and spatial variation of globally defined surface fields (e.g., O'Connell, 1971), and would be used frequently in the discussions presented in the succeeding text.

1.27.2.2 Evidence for Mantle Flow in Correlations between Internal Structure and Surface Gravity Anomalies

The need for a dynamic interpretation of the surface observables (Figure 2) in terms of very deep-seated convective flow in the mantle is illustrated in Figure 3 in which long-wavelength gravity anomalies are directly compared to seismically inferred lateral heterogeneity in the lower mantle. The large-scale pattern of faster than average shear velocities, which lie below the periphery of the Pacific Ocean (blue-colored regions in Figure 3(b)), has long been interpreted in terms of accumulating lithospheric slabs, which have subducted below the margins of the Pacific Ocean since Mesozoic times (Chase, 1979; Chase and Sprowl, 1983; Richards and Engebretson, 1992). These seismic anomalies, which presumably represent positive density anomalies (i.e., cold subducted slabs), are closely correlated with a broad ringlike pattern of negative gravity anomalies around the periphery of the Pacific Ocean (red-colored regions in Figure 3(a)).

The correlation between long-wavelength seismic heterogeneity in the lower-mantle and surface gravity anomalies was first identified by Dziewonski et al. (1977), and they postulated that a dynamic interpretation in terms of mantle flow could explain the negative sign of the correlation. In a rigid or elastic mantle in which flow is absent, a positive correlation between internal density and surface gravity is expected. However, in a convecting mantle, the gravitational signal of internal density anomalies is opposed by the effect of flow-induced topography at the surface and at the CMB, and this dynamic balance can lead to the observed negative correlation (e.g., Parsons and Daly, 1983; Pekeris, 1935; Richards and Hager, 1984).

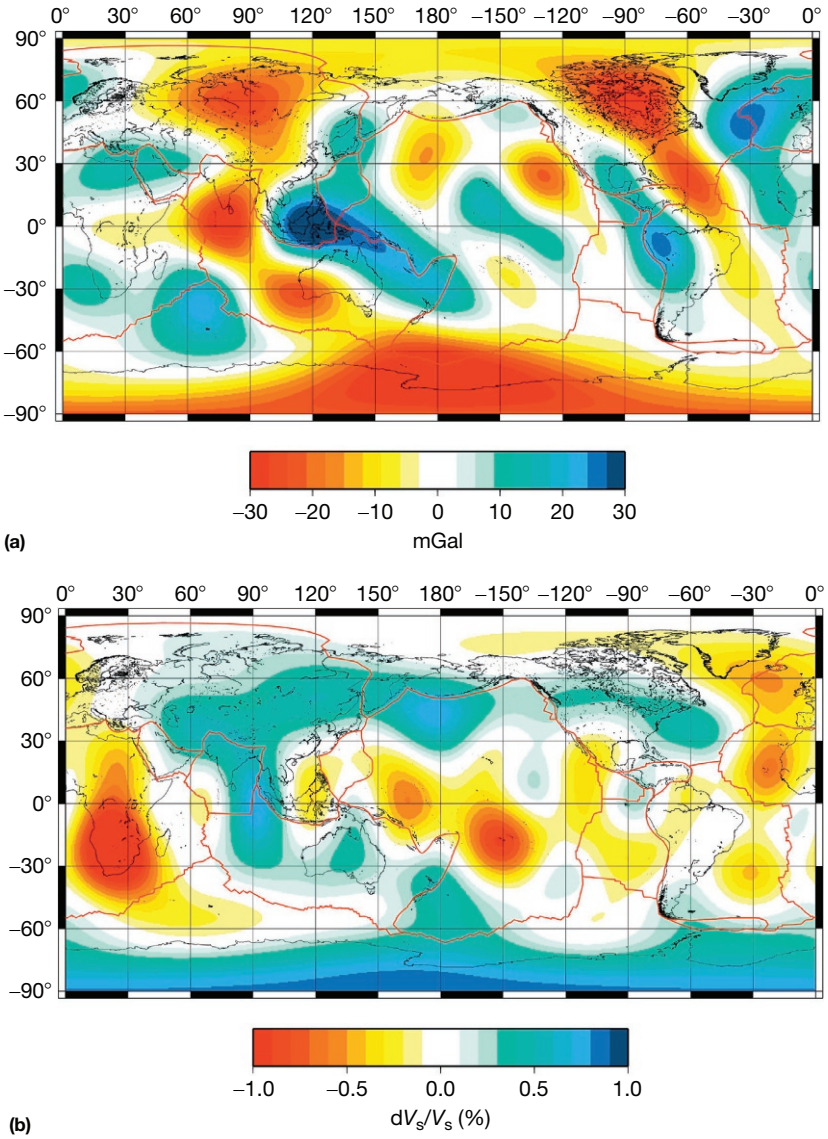

Figure 3 Surface gravity anomalies and deep-mantle heterogeneity. (a) Long-wavelength free-air gravity anomalies derived from the joint geopotential model EGM96 (Lemoine et al., 1998). (b) Long-wavelength seismic shear-velocity anomalies at a depth of 2100 km derived from the tomography model of Grand (2002). Both the gravity and seismic anomaly fields are synthesized from spherical harmonics in the degree range $\ell = 1 - 8$.

It is instructive to consider a more detailed spectral analysis of the correlation between surface gravity anomalies and seismically inferred lateral heterogeneity at different depths in the mantle. The degree correlations shown in Figure 4 indicate which depth ranges in the mantle may be important contributors to the different wavelengths of the surface gravitational field. The strongest positive correlations appear in the transition zone region of the mantle (from ~400 to ~800 km depth), and at the longest wavelength (degree 2), they extend down to about 1400 km depth. The positive sign of these correlations indicates that long-wavelength gravity highs overlie similarly large-scale seismically fast regions located at the base of the upper mantle. Negative degree correlations between long-wavelength seismic and gravity anomalies are found in the near-surface region, down to about 400 km depth and in lower mantle below 1400 km depth (as in Figure 3) where the strongest negative correlations are found. These depth-dependent degree correlations, obtained on the basis of long-wavelength tomography models derived more than a decade ago, are robust observations, which have been verified using the latest seismic tomographic inferences of 3-D mantle structure (Ricard et al., 2006).

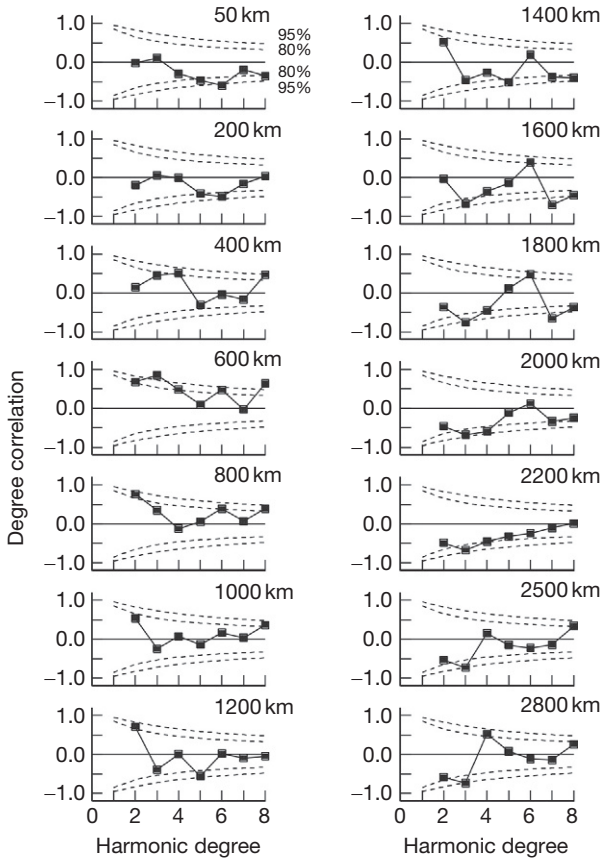

Figure 4 Depth-dependent correlations between 3-D mantle structure and gravity anomalies. Each frame shows the degree correlations between surface gravity anomalies and lateral variations in seismic shear velocity at a particular depth in the mantle. The seismic anomalies are derived from an earlier long-wavelength tomography model *SH8/U4L8* (Forte et al., 1993a). Adapted from Forte AM, Dziewonski AM, and Woodward RL (1993a) Aspherical structure of the mantle, tectonic plate motions, nonhydrostatic geoid, and topography of the core-mantle boundary. In: LeMouël J-L, Smylie DE, and Herring T (eds.) *Dynamics of the Earth's Deep Interior and Earth Rotation*. Geophysical Monograph Series, vol. 72, pp. 135–166, Washington, DC: American Geophysical Union.

The correlation between mantle heterogeneity and surface gravity anomalies in a convecting mantle has been shown to be a strong function of the depth dependence of the rheological properties of the mantle (e.g., Forte and Peltier, 1987; Hager, 1984; Hager et al., 1985; Ricard et al., 1984). In particular, as will be discussed further in the succeeding text, the change from positive correlations at the top of the lower mantle to negative correlations at the bottom of lower mantle (Figure 4) can be interpreted in terms of a significant increase in mean viscosity across the mantle. Other surface observables, such as the tectonic plate motions, also provide important constraints on the depth dependence of mantle rheology (e.g., Forte et al., 1991; Ricard and Vigny, 1989). The geodynamic surface observables also provide direct constraints on the 3-D distribution of density anomalies in the mantle, and hence, these observables provide a fundamentally important and independent means of evaluating the extent to which seismic tomography models successfully resolve the lateral heterogeneity in the mantle, which is associated with mantle convection.

In the next section, the dynamic link between lateral heterogeneity in the mantle and convection-related surface observables will be developed in the theoretical framework of a fluid mechanical model of viscous flow in the mantle. The reader wishing to skip over this detailed mathematical treatment of the mantle flow theory is encouraged to jump directly to Sections 1.27.2.4 and 1.27.2.5, where the viscous response of the mantle and current mantle viscosity inferences, respectively, are summarized.

1.27.2.3 Fluid Mechanical Modeling of Viscous Mantle Flow

1.27.2.3.1 Governing equations

Laboratory and geologic evidence of the ability of mantle rocks to creep indefinitely over geologic timescales is understood in terms of the existence of atomic-scale defects in the lattice of crystal grains (e.g., Nicolas and Poirier, 1976). If the ambient mantle temperature is sufficiently high, the imposition of nonhydrostatic stresses causes the lattice defects to propagate and thus allows the mantle rocks to creep or 'flow' slowly. This process may be characterized in terms of a single parameter, namely, an effective viscosity (e.g., Weertman, 1978; Weertman and Weertman, 1975).

The characterization of the long-term creep properties of the mantle in terms of an effective viscosity allows us to model the slow flow of the mantle with the conventional hydrodynamic field equations. The hydrodynamic field equations (Landau and Lifshitz, 1959), which express the principles of conservation of mass and momentum, are

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \mathbf{u}) = 0 \qquad [5]$$

$$\rho \frac{\mathrm{d}\mathbf{u}}{\mathrm{d}t} = \nabla \cdot \boldsymbol{\sigma} + \rho \mathbf{g} \qquad [6]$$

in which $\mathbf{u}$ is the velocity field, $\mathrm{d}/\mathrm{d}t = \partial/\partial t + \mathbf{u}\cdot\nabla$ is the total (Lagrangian) time derivative, $\boldsymbol{\sigma}$ is the stress tensor, g is the gravitational acceleration, and ρ is the density.

We may represent the gravitational field $\mathbf{g}$ in terms of a gravitational potential:

$$\mathbf{g} = \nabla\phi \qquad [7]$$

Notice that the sign convention adopted here is opposite to that generally adopted in classical physics, where a *negative* gradient of the potential is used. With this sign convention, Poisson's equation for the relationship between the gravity potential and density is

$$\Delta\phi = -4\pi G\rho \quad (\Delta \equiv \nabla\cdot\nabla) \qquad [8]$$

An explicit expression for the stress tensor is given by

$$\sigma_{ij} = -P\delta_{ij} + \tau_{ij} \qquad [9]$$

$$\text{with } \tau_{ij} = \eta\left(u_{i,j} + u_{j,i} - \frac{2}{3}\delta_{ij}u_{k,k}\right) + \lambda\delta_{ij}u_{k,k} \qquad [10]$$

where τ_{ij} is the viscous stress tensor, δ_{ij} is the identity tensor, P is the total pressure, η and λ are the *isotropic* viscosity coefficients, and $u_{i,j} = \partial u_i/\partial x_j$ represents the derivative of the velocity components i with respect to the coordinate direction j.

A number of simplifications are possible when applying the earlier field equations to the problem of flow in the mantle:

- Since mantle rocks creep much slower than the acoustic velocity in the mantle, we can safely ignore the term $\partial\rho/\partial t$ in the conservation of mass (eqn [5]), and we thus have the following anelastic-liquid approximation:

$$\nabla\cdot(\rho\mathbf{u}) = 0 \qquad [11]$$

This simplification will explicitly rule out acoustic waves as solutions of the flow equations.

- The second viscosity coefficient λ in the viscous stress tensor τ_{ij} describes the dissipation associated with change in fluid volume (density). This volume dissipation may be neglected if the changes in fluid volume occur on timescales that are much longer than for molecular relaxation processes (Landau and Lifshitz, 1959), and this is certainly true for mantle flow. Therefore, the viscous stress tensor τ_{ij} will be purely deviatoric:

$$\tau_{ij} = \eta\left(u_{i,j} + u_{j,i} - \frac{2}{3}\delta_{ij}u_{k,k}\right) \qquad [12]$$

- We will further assume a Newtonian (i.e., linear) rheology, in which the mantle viscosity η is not a function of stress or strain rate. This assumption is not necessarily appropriate for the mantle (particularly in high-stress regions, such as subduction zones), but it will greatly simplify the mathematical resolution of the flow equations, which is presented in the succeeding text.
- A major simplification, from a purely mathematical standpoint, derives from the assumption that mantle viscosity varies only with radius. Although this assumption will significantly simplify the mathematical treatment of the flow theory, it may have important physical implications for the dynamics of buoyancy-induced flow in the mantle (e.g., Richards and Hager, 1989). These implications have been examined previously in the context of global-scale flow in 3-D spherical geometry (e.g., Čadek and Fleitout, 2003; Forte and Peltier, 1994; Martinec et al., 1993; Moucha et al., 2007; Ricard et al., 1988; Zhang and Christensen, 1993) and they will be discussed later.
- A fundamental physical simplification arises from the very large value of the effective viscosity in the mantle. We may nondimensionalize the conservation of momentum equation with the following variable transformations:

$$\left.\begin{aligned}(x, y, z) &= (\mathrm{d}x, \mathrm{d}y, \mathrm{d}z)\\ t &= \left(d^2/\kappa_o\right)t\\ \rho = \rho_o\rho;& g = g_o g; \eta = \eta_o\eta\end{aligned}\right\} \qquad [13]$$

where the original variables are on the left and the nondimensional ones are on the right. Quantities d, κ_o, ρ_o, η_o, g_o are characteristic scales for length, thermal diffusivity, density, viscosity, and gravitational acceleration, respectively, in the mantle. The use, in eqn [13], of a thermal diffusion timescale

$$t_\kappa = d^2/\kappa_o \qquad [14]$$

is appropriate since we are dealing with mantle flow arising from thermal convection. The stress tensor and pressure have the same physical units (see expression [9]), and hence, their nondimensional transformation is

$$P = (\rho_o g_o d)\, P \quad \text{and} \quad \boldsymbol{\tau} = (\rho_o g_o d)\boldsymbol{\tau} \qquad [15]$$

where, again, the original quantities are on the left and the nondimensional ones on the right. By virtue of the constitutive relation [12], and expression [15], we obtain the following nondimensional transformation for the flow variable:

$$\mathbf{u} = \frac{\rho_o g_o d^2}{\eta_o}\mathbf{u} \qquad [16]$$

or, equivalently,

$$\mathbf{u} = g_o t_v \mathbf{u} \qquad [17]$$

where $t_v = d^2/v_o$ is the timescale for viscous diffusion of momentum and $v_o = \eta_o/\rho_o$ is the kinematic viscosity. Finally, substitution of expressions [9] and [13]–[17] into [6] yields the following nondimensional momentum conservation equation:

$$\rho\left[\frac{1}{Pr}\frac{\partial\mathbf{u}}{\partial t} + \left(\frac{g_o}{d}\right)t_v^2\mathbf{u}\cdot\nabla\mathbf{u}\right] = \nabla\cdot\boldsymbol{\tau} - \nabla P + \rho\mathbf{g} \qquad [18]$$

in which $Pr = t_\kappa/t_v$ is the Prandtl number, which characterizes the ratio of temperature and momentum diffusion timescales.

To assess the importance of the terms on the left-hand side of eqn [18], we assume the following values for the scaling variables: $d = 3\times10^6$ m (for whole-mantle flow), $\rho_o = 3.3\times10^3$ kg m^{-3}, $g_o = 10$ m s^{-2}, $\kappa_o = 1.5\times10^{-6}$ m^2 s^{-1}, and $\eta_o = 10^{21}$ Pa s, and we thus obtain

$$\begin{aligned}&t_v = 3\times10^{-5}\,\mathrm{s};\ t_\kappa = 6\times10^{18}\,\mathrm{s};\ \frac{g_o}{d} = 3.3\times10^{-6}\,\mathrm{s}^{-2};\\ &Pr = 2\times10^{23}\end{aligned} \qquad [19]$$

The key quantity here is the characteristic time for momentum diffusion t_v, which is very small (i.e., mantle flow will

come to a complete halt in much less than a millisecond if all buoyancy forces are suddenly removed).

The vanishingly small momentum diffusion time, and hence the very large Prandtl number, implies that the inertial forces ($\rho \mathrm{d}\mathbf{u}/\mathrm{d}t$) in the momentum conservation equation are completely negligible. Therefore, using expression [7], the momentum conservation (eqn [6]) simplifies to

$$\nabla\cdot\boldsymbol{\tau} - \nabla P + \rho\nabla\phi = \mathbf{0} \qquad [20]$$

Equation [20] shows that in the absence of inertia, there must at all times be a balance between the buoyancy forces $\rho\mathbf{g}$ and the forces of viscous dissipation described by $\nabla\cdot\boldsymbol{\tau}$. In other words, any changes in internal buoyancy forces will instantly produce changes in fluid flow: this is a consequence of the essentially instantaneous diffusion of momentum in the mantle.

We may define an idealized hydrostatic reference state for the mantle, which corresponds to the absence of any internal flow or deformation (i.e., $\mathbf{u} = \mathbf{0}$). In this situation, the deviatoric stress field τ vanishes and the momentum conservation (eqn [6]) reduces to

$$-\nabla P_o + \rho_o \nabla\phi_o = 0 \qquad [21]$$

in which P_o, ρ_o, and ϕ_o are the pressure, density, and gravity potentials in the hydrostatic state. Poisson's eqn [8] for a hydrostatic planet is

$$\Delta\phi_o = -4\pi G\rho_o \qquad [22]$$

We assume that in a dynamic mantle, with a nonvanishing mantle flow $\mathbf{u}$, the pressure, density, and gravity potentials will be perturbed as follows:

$$P = P_o + P_1 \quad \rho = \rho_o + \rho_1 \quad \phi = \phi_o + \phi_1 \qquad [23]$$

in which all perturbations are assumed to be small, that is,

$$\left|\frac{P_1}{P_o}\right| \ll 1 \quad \left|\frac{\rho_1}{\rho_o}\right| \ll 1 \quad \left|\frac{\phi_1}{\phi_o}\right| \ll 1$$

If we now substitute the perturbed variables [23] into the equations of mass and momentum conservation ([11]–[20]) and Poisson's eqn [8] and then subtract out the hydrostatic reference (eqns [21] and [22]), we finally obtain the following set of first-order accurate, perturbed equations for mantle flow dynamics:

$$\text{mass conservation} \quad \nabla\cdot(\rho_o\mathbf{u}) = 0 \qquad [24]$$

$$\text{momentum conservation} \quad \nabla\cdot\boldsymbol{\tau} - \nabla P_1 + \rho_o\nabla\phi_1 + \rho_1\nabla\phi_o = \mathbf{0} \qquad [25]$$

$$\text{gravity} \quad \boldsymbol{\Delta}\phi_1 = -4\pi G\rho_1 \qquad [26]$$

Notice in eqn [25] that in addition to the driving buoyancy forces ($\rho_1\nabla\phi_o$), there also exist self-gravitational loads ($\rho_o\nabla\phi_1$) due to the perturbed gravitational field. The equations in the preceding text must be supplemented by the linear relationship [12] between stress and strain rate, which is valid for an isotropic rheology:

$$\text{Newtonian constitutive equation} \quad \boldsymbol{\tau} = \eta\left(\vec{\nabla}\mathbf{u} + \mathbf{u}\overleftarrow{\nabla} - \frac{2}{3}\,\mathbf{I}\,\nabla\cdot\mathbf{u}\right) \qquad [27]$$

1.27.2.3.2 Spectral treatment of the mantle flow equations

A classical technique for solving the dynamic flow equations in 3-D spherical geometry is the spectral Green function method, in which all flow variables are expressed in terms of spherical harmonic basis functions introduced in eqn [1] (e.g., Forte and Peltier, 1987, 1991; Hager and O'Connell, 1981; Ricard et al., 1984; Richards and Hager, 1984). The spectral Green functions provide a very convenient mathematical description of the instantaneous relationship between the mantle density anomalies and the viscous flow field, as well as all surface manifestations of the internal flow dynamics.

The spectral method is employed here for solving the coupled equations of mass, momentum, and gravity conservation (eqns [24]–[26]), supplemented by the viscous constitutive relation [27]. The method follows that initially developed by Forte and Peltier (1991) for gravitationally consistent compressible flow in spherical geometry. Other treatments of compressible mantle flow in spherical geometry have been presented by Corrieu et al. (1995), Panasyuk et al. (1996), and Defraigne (1997). An overview of the method is presented later, and we refer to Forte and Peltier (1991), Forte and Woodward (1997a), and Forte (2000) for complete details.

One begins by rewriting eqns [24]–[27], in the following Cartesian tensor form:

$$\left.\begin{aligned} u_{k,k} &= -\frac{\dot{\rho}_o}{\rho_o}u_r \\ \sigma_{ij,j} + \rho_o(\phi_1)_{,i} - \rho_1 g_o\hat{r} &= 0 \\ \sigma_{ij} &= -P_1\delta_{ij} + \eta\left(u_{i,j} + u_{j,i} - \frac{2}{3}\delta_{ij}u_{k,k}\right) \\ (\phi_1)_{,kk} &= -4\pi G\rho_1 \end{aligned}\right\} \qquad [28]$$

in which $\dot{\rho}_o = \mathrm{d}\rho_o/\mathrm{d}r$, $u_r = \hat{\mathbf{r}}\cdot\mathbf{u}$ and $(\phi_o)_{,i} = -g_o\hat{r}$. It should also be noted that in these equations, the total stress tensor $\boldsymbol{\sigma}$ is used, rather than the deviatoric stress $\boldsymbol{\tau}$ used in [25].

The determination of a solution to the system of tensor (eqn [28]) in spherical geometry may be greatly simplified by using an elegant mathematical technique described by Phinney and Burridge (1973). Following their technique, one introduces a new coordinate system defined by the following complex basis vectors in spherical geometry:

$$\left.\begin{aligned} \hat{\boldsymbol{e}}_- &= \frac{1}{\sqrt{2}}\left(\hat{\boldsymbol{\vartheta}} - \imath\,\hat{\boldsymbol{\varphi}}\right) \\ \hat{\boldsymbol{e}}_0 &= \hat{\boldsymbol{r}} \\ \hat{\boldsymbol{e}}_+ &= -\frac{1}{\sqrt{2}}\left(\hat{\boldsymbol{\vartheta}} + \imath\,\hat{\boldsymbol{\varphi}}\right) \end{aligned}\right\} \qquad [29]$$

in which $\imath = \sqrt{-1}$ and $\hat{\boldsymbol{r}}, \hat{\boldsymbol{\vartheta}}, \hat{\boldsymbol{\varphi}}$ are the unit basis vectors for the standard spherical polar coordinate system.

Following Phinney and Burridge (1973), all the tensors appearing in the original system [28] are rotated into the

coordinate system defined by [29], thereby yielding the following covariant tensor form of the dynamic equations:

$$\left.\begin{aligned} cu^{\alpha,\beta}e_{\alpha\beta} &= -\frac{\dot{\rho}_o}{\rho_o}u^0 \\ \sigma^{\alpha\beta,\gamma}e_{\beta\gamma} + \rho_o(\phi_1)^{,\alpha} - \rho_1 g_o \delta_0^\alpha &= 0 \\ \sigma^{\alpha\beta} = -P_1 e^{\alpha\beta} + \eta\left(u^{\alpha,\beta}+u^{\beta,\alpha}\right) - \frac{2}{3}\eta\left(u^{\delta,\gamma}e_{\delta\gamma}\right)e^{\alpha\beta} \\ (\phi_1)^{,\alpha\beta}e_{\alpha\beta} &= -4\pi G\rho_1 \end{aligned}\right\} \quad [30]$$

in which the Greek indices denote the coordinate directions in system [29] and therefore range over the values (−1, 0, and +1). The quantities $e^{\alpha\beta}$, $e_{\alpha\beta}$, and δ^α_β are the contravariant, covariant, and mixed tensor representations of the Cartesian identity tensor δ_{ij}.

The velocity (u^α) and stress ($\sigma^{\alpha\beta}$) components are expanded in terms of the generalized spherical functions Y_ℓ^{Nm} (Phinney and Burridge, 1973) such that

$$\begin{aligned} u^-(r,\theta,\phi) &= \sum_{\ell,m} U_\ell^{-m}(r)Y_\ell^{-1m}(\theta,\phi) \\ u^0(r,\theta,\phi) &= \sum_{\ell,m} U_\ell^{0m}(r)Y_\ell^{0m}(\theta,\phi) \\ u^+(r,\theta,\phi) &= \sum_{\ell,m} U_\ell^{+m}(r)Y_\ell^{+1m}(\theta,\phi) \end{aligned} \quad [31]$$

$$\sigma^{\alpha\beta}(r,\theta,\phi) = \sum_{\ell,m} T_\ell^{\alpha\beta m}(r)Y_\ell^{(\alpha+\beta)m}(\theta,\phi) \quad (\alpha,\beta=-1,0,+1) \quad [32]$$

All scalar fields involved in the governing eqn [30] are expanded in terms of ordinary spherical harmonics. For example,

$$\begin{aligned} \rho_1(r,\theta,\phi) &= \sum_{\ell,m}(\rho_1)_\ell^m(r)Y_\ell^m(\theta,\phi) \\ \phi_1(r,\theta,\phi) &= \sum_{\ell,m}(\phi_1)_\ell^m(r)Y_\ell^m(\theta,\phi) \end{aligned} \quad [33]$$

where $Y_\ell^m \equiv Y_\ell^{0m}$.

We can simplify subsequent numerical computations by nondimensionalizing all relevant physical variables using the following transformations:

$$\left.\begin{aligned} r = \mathrm{d}r,\ g_o(r) = g_o g(r),\ \ \eta(r) = \eta_o\eta(r),\ \ \rho_1 = (\Delta\rho)\rho_1, \\ T^{\alpha\beta} = (\Delta\rho g_o d)\ T^{\alpha\beta},\ \ U^\alpha = \left(\frac{\Delta\rho g_o d^2}{\eta_o}\right)U^\alpha,\ \ \phi_1 = \left(\frac{4\pi G R_o}{2\ell+1}\Delta\rho d\right)\phi_1 \end{aligned}\right\} \quad [34]$$

in which the original variables are on the left of each equation and the nondimensional variables are on the right. The scaling quantities we have used are defined as follows:

$d = 2888$ km	≡	radial thickness of mantle
$g_o = 9.82$ ms^{-2}	≡	mean surface gravitational acceleration
$\Delta\rho = 0.1$ Mgm^{-3}	≡	characteristic subducted slab density anomaly
$\eta_o = 10^{21}$ Pa s	≡	Haskell (1935) reference value
$R_o = 6371$ km	≡	mean surface radius of Earth

Substituting expressions [31]–[33] into the flow eqn [30], and using the nondimensionalization scheme [34] as well as the orthogonality properties of the generalized spherical harmonics (as in Phinney and Burridge, 1973), yields two independent systems of flow equations. The first system, governing a poloidal geometry of flow, consists of the following six coupled, first-order, ordinary differential equations:

$$\frac{\mathrm{d}}{\mathrm{d}r}\begin{pmatrix} U^0 \\ U^P \\ T^0 \\ T^P \\ \phi_1 \\ g_1 \end{pmatrix} = \begin{pmatrix} -\frac{[2+r(\dot{\rho}_o/\rho_o)]}{r} & \frac{\Omega_1}{r} & 0 & 0 & 0 & 0 \\ -\frac{2\Omega_1}{r} & \frac{1}{r} & 0 & \frac{\eta_o}{\eta} & 0 & 0 \\ \frac{4[3+r(\dot{\rho}_o/\rho_o)]}{r^2}\frac{\eta}{\eta_o} & -\frac{6\Omega_1}{r^2}\frac{\eta}{\eta_o} & 0 & \frac{\Omega_1}{r} & \frac{3}{2\ell+1}\frac{\dot{\rho}_o}{\overline{\rho}} & 0 \\ -\frac{4\Omega_1[3+r(\dot{\rho}_o/\rho_o)]}{r^2}\frac{\eta}{\eta_o} & \frac{2[\Omega_2^2+3\Omega_1^2]}{r^2}\frac{\eta}{\eta_o} & -\frac{2\Omega_1}{r} & -\frac{3}{r} & 0 & 0 \\ 0 & 0 & 0 & 0 & 0 & 1 \\ 0 & 0 & 0 & 0 & \frac{\ell(\ell+1)}{r^2} & -\frac{2}{r} \end{pmatrix} \begin{pmatrix} U^0 \\ U^P \\ T^0 \\ T^P \\ \phi_1 \\ g_1 \end{pmatrix} + \begin{pmatrix} 0 \\ 0 \\ g(r) \\ 0 \\ 0 \\ (-2\ell+1)\frac{d}{R_o} \end{pmatrix}\frac{\rho_1(r)}{\Delta\rho} \quad [35]$$

in which $\dot{\rho}_o = \mathrm{d}\rho_o/\mathrm{d}r$, $\Omega_1 = [\ell(\ell+1)/2]^{1/2}$, $\Omega_2 = [(\ell-1)(\ell+2)/2]^{1/2}$ and $\overline{\rho}$ is Earth's mean density (5.5143×10^3 kg m^{-3}).

The second system, governing a toroidal geometry of flow, consists of the following two coupled, first-order, ordinary differential equations:

$$\frac{\mathrm{d}}{\mathrm{d}r}\begin{pmatrix} U^T \\ T^T \end{pmatrix} = \begin{pmatrix} \frac{1}{r} & \frac{1}{\eta} \\ \frac{2\Omega_2^2\eta}{r^2} & -\frac{3}{r} \end{pmatrix}\begin{pmatrix} U^T \\ T^T \end{pmatrix} \quad [36]$$

The flow, stress, and gravity variables in the poloidal and toroidal-flow systems ([35], [36]) are all dependent on the same harmonic degree ℓ and order m (this dependence has been dropped for notational convenience). The dependence of these variables on the harmonic coefficients of flow [31], stress [32], and gravitational potential [33] is

$$\begin{aligned} U^P(r) &= U^+(r) + U^-(r) \\ U^T(r) &= U^+(r) - U^-(r) \\ T^0 = T^{00}(r) &+ \frac{3}{2\ell+1}\frac{\rho_0(r)}{\overline{\rho}}\phi_1(r) \\ T^P &= T^{0+}(r) + T^{0-}(r) \\ T^T &= T^{0+}(r) - T^{0-}(r) \end{aligned} \quad [37]$$

1.27.2.3.3 Internal boundary conditions

The determination of a unique solution of the system of flow (eqns [35] and [36]) derived in the preceding section requires the specification of appropriate boundary conditions at the top

and bottom surfaces of the mantle and internal matching conditions at all material interfaces within the mantle. We will consider the latter first since the surface boundary conditions can be obtained as a special case of the internal matching conditions.

The need for internal boundary conditions in solving for mantle flow is evident upon inspection of the depth variation of mantle density $\rho_o(r)$ (see **Figure 5**) given by the PREM seismic reference model (Dziewonski and Anderson, 1981). The PREM density profile is characterized by two major jumps at depths of 400 and 670 km. These density jumps have long been interpreted as manifestations of phase-change boundaries (e.g., Jeanloz and Thompson, 1983), which presumably also affect the depth variation of viscosity at these depths (e.g., Sammis et al., 1977).

We now derive the matching conditions that must be satisfied when characteristic properties of the mantle, in particular density, viscosity, and chemical composition, change very rapidly across phase-change or chemical horizons in the mantle. We will approximate such rapid changes as mathematical discontinuities. Denoting the mean (i.e., horizontally averaged) location of the internal material boundary as $r=r_i$, geographic variations in the radial location (i.e., deflections) of the boundary are then represented by

$$r = r_i + \delta r_i, \quad \text{where we assume } \left|\frac{\delta r_i}{r_i}\right| \ll 1 \qquad [38]$$

A discontinuous change in density across an internal boundary implies that

$$\left(\frac{\mathrm{d}\rho_o}{\mathrm{d}r}\right)_{r=r_i} = \left[\rho_o\left(r_i^+\right) - \rho_o\left(r_i^-\right)\right]\delta(r-r_i) \qquad [39]$$

By virtue of this last expression, the density perturbation due to the boundary deflection δr_i is given by the following sheet-mass anomaly:

$$\delta\rho_i = -\left(\frac{\mathrm{d}\rho_o}{\mathrm{d}r}\right)_{r=r_i}\delta r_i = -\left[\rho_o\left(r_i^+\right) - \rho_o\left(r_i^-\right)\right]\delta r_i\delta(r-r_i) \qquad [40]$$

This last expression shows that an internal boundary deflection gives rise to a mantle buoyancy source, which may be approximated by a delta-function load and the corresponding density perturbation is, in nondimensional terms:

$$\frac{\rho_1(r)}{\Delta\rho} = -\frac{\left[\rho_o\left(r_i^+\right) - \rho_o\left(r_i^-\right)\right]}{\Delta\rho}\frac{\delta r_i}{d}\delta(r-r_i) \qquad [41]$$

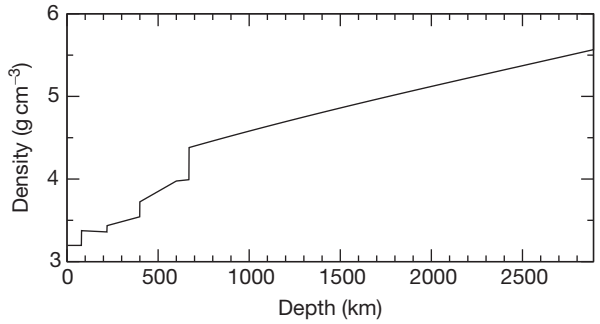

Figure 5 Depth-dependent mean density in the mantle from the PREM seismic reference model (Dziewonski and Anderson, 1981).

This expression shows that from a purely fluid mechanical perspective, the dynamic effect of a deformed phase-change boundary is indistinguishable from integrated buoyancy forces elsewhere in the mantle. If the material interface instead corresponds to a chemical discontinuity in the mantle, the fluid mechanical buoyancy effect is also the same. The main distinction between the deflection-induced buoyancy of phase-change and chemical discontinuities is that the former is controlled by thermodynamics (i.e., the Clapeyron slope), whereas the latter is due to the change in intrinsic chemical buoyancy across the interface.

The matching condition for the radial component of the flow field is obtained by integrating the first row in system [35] from $r_i^- = r_i - \epsilon$ to $r_i^+ = r_i + \epsilon$, taking the limit $\varepsilon \to 0$. In terms of the radial flow variable U^0, this yields the following mass conservation equation:

$$\rho_o\left(r_i^+\right)U^0\left(r_i^+\right) = \rho_o\left(r_i^-\right)U^0\left(r_i^-\right) \qquad [42]$$

where $\rho_o(r_i^+)$ and $\rho_o(r_i^-)$ are the mantle density immediately above and below the material boundary, respectively. If the internal boundary corresponds to a chemical discontinuity, then we must impose a zero radial velocity condition:

$$U^0\left(r_i^+\right) = 0 = U^0\left(r_i^-\right) \qquad [43]$$

The matching condition for the tangential mantle flow velocity is obtained by integrating the second equation in eqn [35], which yields the following continuity of the tangential flow variable U^P:

$$U^P\left(r_i^+\right) = U^P\left(r_i^+\right) \qquad [44]$$

This continuity of tangential flow also applies to the case of an internal chemical boundary.

The internal matching condition for the radial stress T^0 across a deformed material interface is obtained by integrating the third row in system [35], in which we substitute result [41] into the buoyancy force term $\rho_1/\Delta\rho$ in expression [35], thereby yielding

$$T^0\left(r_i^+\right) - T^0\left(r_i^-\right) = \Delta_u(r_i) + \frac{3}{2\ell+1}\left[\frac{\rho_o\left(r_i^+\right) - \rho_o\left(r_i^-\right)}{\bar{\rho}}\right]\phi_1(r_i) - \frac{\left[\rho_o\left(r_i^+\right) - \rho_o\left(r_i^-\right)\right]}{\Delta\rho}\frac{\delta r_i}{d}g(r_i) \qquad [45]$$

in which the term

$$\Delta_u(r_i) = -\frac{2}{r_i}\left(\frac{\eta\left(r_i^+\right) + \eta\left(r_i^-\right)}{\eta_o}\right)\left[U^0\left(r_i^+\right) - U^0\left(r_i^-\right)\right] \qquad [46]$$

arises from the discontinuous change in radial flow (see expression [42]) due to a density jump across an internal (phase-change) boundary. This term vanishes in the case of a chemical discontinuity since expression [43] then applies. The matching condition for the tangential stress T^P is obtained by integrating the fourth equation in eqn [35]:

$$T^P\left(r_i^+\right) - T^P\left(r_i^-\right) = -\Omega_1\Delta_u(r_i) \qquad [47]$$

The term Δ_u gives rise to an apparent discontinuity in tangential stress, and this is again a consequence of our

mathematical treatment of a discontinuous change in radial flow across a material interface. The significance of this apparent jump in tangential stress was first noted by Corrieu et al. (1995), and a subsequent analysis by Forte and Woodward (1997a) determined that the effect of this discontinuity was negligible. In the case of a chemical discontinuity, the term Δ_u vanishes and the tangential stress is then continuous across the interface.

Integration of the fifth row in [35] across the material interface located at mean radius r_i yields the following matching condition for the perturbed gravitational potential:

$$\phi_1(r_i^+) = \phi_1(r_i^-) \quad [48]$$

The matching condition for the perturbed gravitational acceleration is obtained by substituting expression [41] into the buoyancy force term $\rho_1/\Delta\rho$ in [35] and then integrating the sixth row of this system, yielding the following nondimensional expression:

$$g_1(r_i^+) - g_1(r_i^-) = (2\ell+1)\left(\frac{d}{R_o}\right)\frac{[\rho_o(r_i^+) - \rho_o(r_i^-)]}{\Delta\rho}\frac{\delta r_i}{d} \quad [49]$$

in which $g_1 = \mathrm{d}\phi_1/\mathrm{d}r$.

The internal matching conditions for the toroidal components of mantle flow are readily obtained following the same procedure employed for the poloidal flow. Integration of the first row in system [36] yields the following continuity of toroidal flow across any (phase-change or chemical) interface:

$$U^T(r_i^+) = U^T(r_i^-) \quad [50]$$

Similarly, an integration of the second row in [36] yields the following continuity of tangential stress across any internal material interface:

$$T^T(r_i^+) = T^T(r_i^-) \quad [51]$$

1.27.2.3.4 Boundary conditions at Earth's solid surface

It will be assumed that the spherically symmetrical, hydrostatic reference Earth model is overlain by a global ocean layer, which is 3 km thick, as in PREM (Dziewonski and Anderson, 1981). PREM's crust and seismic lithosphere are combined into a single mechanical layer containing the same total mass as the two PREM layers assuming, for simplicity, that both layers deform and move together in response to the buoyancy-driven flow in the mantle. The top surface of the combined crust–lithosphere is located at radius $r = 6368$ km and the base is located at radius 6291 km (i.e., at a depth of 80 km below the surface of the global ocean layer). This redefined lithosphere has mass density of 3.2 Mg m^{-3}.

In view of the very complicated mechanical and rheological properties of the crust and underlying lithosphere, in particular the tectonic plates, it is clear that the flow theory developed here with a purely depth-dependent viscosity cannot provide an adequate representation of the near-surface dynamics. An approximate treatment of the effect of surface tectonic plates is presented in Section 1.27.2.3.7. In the meantime, we will consider here two different boundary conditions of relevance at the solid surface: *free-slip* and *no-slip*.

Earth's bounding surface at $r = a = 6368$ km is a chemical (compositional) boundary across which there can be no flow and hence the matching condition [43] is applicable:

$$U^0(a^-) = 0, \quad \text{for both free-slip \& no-slip} \quad [52]$$

where a^- denotes the radial location $r = a - \varepsilon$. We can, to first-order accuracy, ignore surface deflections (i.e., topography) in specifying the boundary conditions on the flow.

The condition for the surface tangential flow $U^P(a^-)$ in the lithosphere is

$$U^P(a^-) = \begin{cases} U^P(a^-) & \text{to be determined, for free-slip} \\ 0 & \text{for no-slip} \end{cases} \quad [53]$$

In the case of the surface toroidal flow, the boundary condition is

$$U^T(a^-) = V^T \quad [54]$$

in which V^T is determined from the coupling of surface poloidal and toroidal flows due to the presence of rigid surface tectonic plates. The mathematical formulation of this coupling and an explicit expression for V^T are presented in Section 1.27.2.3.7.

We can apply the radial stress T^0 matching condition in [45] to the deformed surface boundary, which, by virtue of conditions [52], becomes

$$T^0(a^-) - T^0(a^+) = \frac{3}{2\ell+1}\left[\frac{\Delta\rho_a}{\bar{\rho}}\right]\phi_1(a^-) - \left[\frac{\Delta\rho_a}{\Delta\rho}\right]\frac{\delta a}{d}g(a) \quad [55]$$

where we have defined the density jump across the solid surface:

$$\Delta\rho_a = \rho_o(a^-) - \rho_o(a^+) = 3.2 - 1.0\ \mathrm{Mg\,m^{-3}} = 2.2\,\mathrm{Mg\,m^{-3}} \quad [56]$$

and where we have also invoked the universally valid condition [48] for the vertical continuity of the perturbed gravitational potential.

In expression [55], $T^0(a^+)$ corresponds to the radial stress in the global ocean layer. If we assume that the viscosity in the global ocean layer is negligible (i.e., $\eta/\eta_o \to 0$), then the second row in system [35] yields

$$T^P(r) = 0, \text{throughout the ocean layer} \quad [57]$$

and therefore, by virtue of this result, the fourth row in system [35] yields

$$T^0(r) = 0, \text{throughout the ocean layer} \quad [58]$$

Substituting result [58] into expression [55] yields the desired radial stress boundary condition at the surface:

$$T^0(a^-) = \frac{3}{2\ell+1}\left[\frac{\Delta\rho_a}{\bar{\rho}}\right]\phi_1(a^-) - \left[\frac{\Delta\rho_a}{\Delta\rho}\right]\frac{\delta a}{d}g(a) \text{ valid for free-slip \& no-slip} \quad [59]$$

in which δa is the flow-induced vertical deflection of the solid surface (i.e., dynamic surface topography).

The condition for the surface poloidal tangential stress $T^P(a^-)$ is as follows:

$$T^P(a^-) = \begin{cases} 0 & \text{for free-slip} \\ T^P(a^-) & \text{to be determined, for no-slip} \end{cases} \quad [60]$$

and the condition for the surface toroidal tangential stress is

$$T^T(a^-) = T^T(a^-) \text{ to be determined} \quad [61]$$

On the basis of the general result [48], and using result [49], the surface matching conditions for the perturbed gravitational potential and acceleration are

$$\phi_1(a^-) = \phi_1(a^+) \quad [62]$$

$$g_1(a^-) = g_1(a^+) + (2\ell+1)\left(\frac{d}{R_o}\right)\left[\frac{\Delta\rho_a}{\Delta\rho}\right]\frac{\delta a}{d} \quad [63]$$

The ocean-layer potential and gravitational fields $\phi_1(a^+)$ and $g_1(a^+)$, respectively, are not independent of each other, and as shown in Forte and Peltier (1991), they are both related to the perturbed potential at the surface of the global ocean layer, $\phi_1(r=R_o)$:

$$\phi_1(a^+) = P_\ell \phi_1(R_o) \quad [64]$$

$$g_1(a^+) = G_\ell \phi_1(R_o) \quad [65]$$

in which the ocean-layer response functions P_ℓ and G_ℓ are as follows:

$$P_\ell = \left(\frac{R_o}{a}\right)^{\ell+1} - \frac{3}{2\ell+1}\frac{\rho_w}{\overline{\rho}}\left[\left(\frac{R_o}{a}\right)^{\ell+2} - \left(\frac{a}{R_o}\right)^{\ell-1}\right] \quad [66]$$

$$G_\ell = -(\ell+1)\frac{d}{R_o}\left(\frac{R_o}{a}\right)^{\ell+2} + \frac{3}{2\ell+1}\frac{\rho_w}{\overline{\rho}}\frac{d}{R_o}\left[(\ell+1)\left(\frac{R_o}{a}\right)^{\ell+3} + \ell\left(\frac{a}{R_o}\right)^{\ell-2}\right] \quad [67]$$

in which $\rho_w \equiv \rho(a^+) = 1$ Mg m^{-3} is the density of the global ocean layer.

Substitution of results [64] and [65] into expressions [62] and [63] yields the complete surface boundary conditions for the gravitational variables:

$$\phi_1(a^-) = P_\ell \phi_1(R_o), \quad \text{valid for free-slip \& no-slip} \quad [68]$$

$$g_1(a^-) = G_\ell \phi_1(R_o) + (2\ell+1)\left(\frac{d}{R_o}\right)\left[\frac{\Delta\rho_a}{\Delta\rho}\right]\frac{\delta a}{d}, \quad \text{valid for free-slip \& no-slip} \quad [69]$$

It should be noted that expression [68] should also be substituted into the radial stress condition [59].

The complete set of free-slip and no-slip surface boundary conditions, in terms of the poloidal-flow vector $\mathbf{v}(r) = (U^0(r), U^P(r), T^0(r), T^P(r), \phi_1(r), g_1(r))^{Tr}$ (where Tr denotes transposition) employed in system [35], is as follows:

Free-slip:

$$\mathbf{v}(a^-) = U^P(a^-)\mathbf{y}_1 + \phi_1(R_o)\mathbf{y}_2 + \frac{\Delta\rho_a}{\Delta\rho}\frac{\delta a}{d}\mathbf{y}_3 \quad [70]$$

in which the surface basis vectors are

$$\mathbf{y}_1 = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} \quad \mathbf{y}_2 = \begin{pmatrix} 0 \\ 0 \\ \frac{3}{2\ell+1}\frac{\Delta\rho_a}{\overline{\rho}}P_\ell \\ 0 \\ P_\ell \\ G_\ell \end{pmatrix} \quad \mathbf{y}_3 = \begin{pmatrix} 0 \\ 0 \\ -g(a) \\ 0 \\ 0 \\ (2\ell+1)\left(\frac{d}{R_o}\right) \end{pmatrix} \quad [71]$$

No-slip:

$$\mathbf{v}(a^-) = T^P(a^-)\mathbf{y}_1' + \phi_1(R_o)\mathbf{y}_2 + \frac{\Delta\rho_a}{\Delta\rho}\frac{\delta a}{d}\mathbf{y}_3 \quad [72]$$

in which the surface basis vectors are

$$\mathbf{y}_1' = \begin{pmatrix} 0 \\ 0 \\ 0 \\ 1 \\ 0 \\ 0 \end{pmatrix} \text{ and } \mathbf{y}_2, \mathbf{y}_3 \text{ are defined in [71]} \quad [73]$$

The surface boundary conditions ([54], [61]) for the toroidal-flow vector $\mathbf{u}(r) = [U^T(r), T^T(r)]^{Tr}$, which is governed by system [36], are

$$\mathbf{u}(a^-) = V^T\mathbf{z}_1 + T^T(a^-)\mathbf{z}_2 \quad [74]$$

in which the two surface basis vectors are

$$\mathbf{z}_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \quad \mathbf{z}_2 = \begin{pmatrix} 0 \\ 1 \end{pmatrix} \quad [75]$$

1.27.2.3.5 Boundary conditions at CMB

The derivation of the boundary conditions that apply at the CMB, located at mean radius $r = b = 3480$ km, is almost identical to the derivation for the surface boundary conditions in the preceding section. The liquid outer core is regarded as having negligible viscosity relative to the mantle, and hence, the CMB is treated as a purely free-slip boundary. The only difference concerns the application of gravitational matching conditions at $r = b$, since we must now deal with the interaction between a deformed CMB and a compressible, hydrostatic core.

A detailed treatment of the gravitational perturbations maintained in a hydrostatic core is presented in Forte and Peltier (1991), where it is shown that perturbed gravitational acceleration at the top of the core (i.e., immediately below the CMB) is determined by the perturbed potential at the bottom of the mantle (i.e., immediately above the CMB), as follows:

$$g_1(b^-) = R_\ell \phi_1(b^+)$$

where b^- denotes the radial location $r = b - \varepsilon$ (i.e., bottom side of the CMB) and b^+ denotes $r = b + \varepsilon$ (i.e., topside of the CMB). R_ℓ is a numerically determined coefficient, which is obtained on the basis of the compressible density profile throughout the core (Forte and Peltier, 1991).

The complete set of free-slip CMB boundary conditions in terms of the poloidal-flow vector $\mathbf{v}(r) = [U^0(r), U^p(r), T^0(r), T^P(r), \phi_1(r), g_1(r)]^{Tr}$ in system [35] is

$$\mathbf{v}(b^+) = U^P(b^+)\mathbf{x}_1 + \phi_1(b^+)\mathbf{x}_2 + \frac{\Delta\rho_b}{\Delta\rho}\frac{\delta b}{d}\mathbf{x}_3 \quad [76]$$

in which the CMB basis vectors are

$$\mathbf{x}_1 = \begin{pmatrix} 0 \\ 1 \\ 0 \\ 0 \\ 0 \\ 0 \end{pmatrix} \quad \mathbf{x}_2 = \begin{pmatrix} 0 \\ 0 \\ \frac{3}{2\ell+1}\frac{\Delta\rho_b}{\overline{\rho}} \\ 0 \\ 1 \\ R_\ell \end{pmatrix} \quad \mathbf{x}_3 = \begin{pmatrix} 0 \\ 0 \\ -g(b) \\ 0 \\ 0 \\ (2\ell+1)\left(\frac{d}{R_o}\right) \end{pmatrix} \quad [77]$$

where $\Delta\rho_b = \rho_o(b^+) - \rho(b^-) = -4.434\ \text{Mg m}^{-3}$ is the density jump across the CMB and δb is the deflection (i.e., dynamic topography) of the CMB.

The free-slip CMB boundary condition for the toroidal-flow vector $\mathbf{u}(r) = [U^T(r),\ T^T(r)]^{Tr}$ in system [36] is

$$\mathbf{u}(b^+) = U^T(b^+)\mathbf{w}_1 \qquad [78]$$

in which the CMB basis vector is

$$\mathbf{w}_1 = \begin{pmatrix} 1 \\ 0 \end{pmatrix} \qquad [79]$$

1.27.2.3.6 Determining viscous flow Green functions

The solution to the system of flow (eqn [35]) may be expressed in terms of Green functions, which relate the poloidal-flow velocity and the stress tensor at an arbitrary radius $r = r_0$ to a delta-function density load $\rho_1(r) = \delta(r - r')$ at any other radius $r = r'$.

For arbitrarily complex density (e.g., as in PREM) and viscosity profiles, the poloidal-flow system of eqn [35] must be integrated numerically. When $r \neq r'$, this linear system of equations is homogeneous:

$$\frac{\mathrm{d}}{\mathrm{d}r}\mathbf{v}(r) = \mathbf{M}_P(r)\mathbf{v}(r),\ \text{(when } r \neq r') \qquad [80]$$

in which $\mathbf{M}_P(r)$ is the 6×6 matrix appearing in system [35]. We can propagate each of the surface boundary vectors $\mathbf{y}_i$ ($i = 1, 2, 3$) in [71] or [73], by numerically integrating [80] from the surface ($r = a^-$) downward to $r = r'$, stopping along the way at all internal material boundaries ($r = r_i$) where we apply the internal matching conditions described previously (Section 1.27.2.3.3). We can similarly propagate each of the CMB basis vectors $\mathbf{x}_i$ ($i = 1, 2, 3$) in [77] from the CMB ($r = b^+$) upward to $r = r'$. The basic procedure is summarized schematically in Figure 6.

At the location $r = r'$ of the delta-function load, we apply the matching conditions [42], [44], [45], and [47]–[49]. For each of these matching conditions, we employ the corresponding components of the poloidal-flow vectors $\mathbf{v}(r'_+)$ and $\mathbf{v}(r'_-)$, which are obtained from expressions [70], [72], and [76]:

$$\mathbf{v}(r'_+) = \begin{Bmatrix} U^P(a^-)\mathbf{y}_1(r'_+) \\ T^P(a^-)\mathbf{y}'_1(r'_+) \end{Bmatrix} + \phi_1(R_o)\mathbf{y}_2(r'_+) + \frac{\Delta\rho_a}{\Delta\rho}\frac{\delta a}{d}\mathbf{y}_3(r'_+) \qquad [81]$$

and

$$\mathbf{v}(r'_-) = U^P(b^+)\mathbf{x}_1(r'_-) + \phi_1(b^+)\mathbf{x}_2(r'_-) + \frac{\Delta\rho_b}{\Delta\rho}\frac{\delta b}{d}\mathbf{x}_3(r'_-) \qquad [82]$$

in which the surface and CMB basis vectors, $\mathbf{y}_i(r'_+)$ and $\mathbf{x}_i(r'_-)$, have been obtained by the numerical integration of [80], as outlined earlier. The application of the six matching conditions then yields the following system of equations:

$$\mathbf{A}\mathbf{p} = \boldsymbol{\delta}_p \qquad [83]$$

in which

$$\mathbf{p} = \begin{pmatrix} U^P(a^-)\ \text{or}\ T^P(a^-) \\ \phi_1(R_o) \\ \dfrac{\Delta\rho_a}{\Delta\rho}\dfrac{\delta a}{d} \\ U^P(b^+) \\ \phi_1(b^+) \\ \dfrac{\Delta\rho_b}{\Delta\rho}\dfrac{\delta b}{d} \end{pmatrix} \quad \text{and} \quad \boldsymbol{\delta}_p = \begin{pmatrix} 0 \\ 0 \\ g(r') \\ 0 \\ 0 \\ -(2\ell+1)\dfrac{d}{R_o} \end{pmatrix} \qquad [84]$$

Each column of the 6×6 matrix $\mathbf{A}$ in [83] involves the corresponding basis vectors $\mathbf{y}_i(r'_+)$ and $\mathbf{x}_i(r'_-)$ in [81] and [82].

For any given position $r = r'$ of the delta-function load, we obtain a system of equations given by [83], which can be simply solved to find the unknown vector $\mathbf{p}$. The elements of $\mathbf{p}$ define the poloidal-flow impulse response (kernel) functions of the mantle, which are discussed in Section 1.27.2.4.

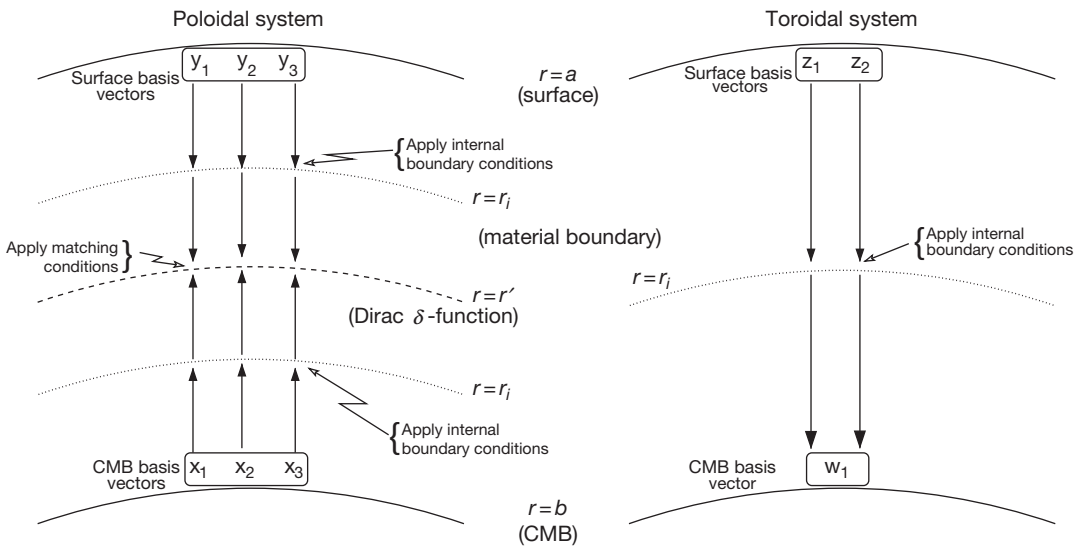

Figure 6 Numerical integration of poloidal-flow system of eqn [35] (left) and toroidal-flow system of eqn [36] (right). The poloidal-flow basis vectors $\mathbf{y}_i$ and $\mathbf{x}_i$ are defined in expressions [71], [73], and [77]. The toroidal-flow basis vectors are defined in expressions [75] and [79].

The toroidal-flow system [36] may be written as the following homogeneous equation:

$$\frac{\mathrm{d}}{\mathrm{d}r}\mathbf{u}(r) = \mathbf{M}_T(r)\mathbf{u}(r) \qquad [85]$$

in which $\mathbf{M}_T(r)$ is the 2×2 matrix appearing in system [36]. We can propagate each of the surface boundary vectors $\mathbf{z}_i$ $(i=1, 2)$ in [75], by numerically integrating [85] from the surface $(r=a^-)$ downward to $r=b^+$, stopping along the way at all internal material boundaries $(r=r_i)$ where we apply the internal matching conditions [50] and [51]. The basic procedure is summarized schematically in Figure 6. The resulting flow vector $\mathbf{u}(b^+)$ is

$$\mathbf{u}(b^+) = V^T\mathbf{z}_1(b^+) + T^T(a^-)\mathbf{z}_2(b^+) \qquad [86]$$

which must be matched to the toroidal flow in expression [79]

$$\mathbf{u}(b^+) = U^T(b^+)\mathbf{w}_1 \qquad [87]$$

We thereby obtain the following simple system:

$$\mathbf{B}\mathbf{t} = \boldsymbol{\delta}_t \qquad [88]$$

in which

$$\mathbf{t} = \begin{pmatrix} U^T(b^+) \\ T^T(a^-) \end{pmatrix} \quad \text{and} \quad \boldsymbol{\delta}_t = V^T\mathbf{z}_1(b^+) \qquad [89]$$

Each column of the 2×2 matrix $\mathbf{B}$ in [88] involves the corresponding basis vectors $\mathbf{w}_1$ and $-\mathbf{z}_2$ in [86] and [87]. Expression [88] shows that the toroidal flow throughout the mantle is 'driven' by the surface toroidal flow V^T generated by rotating tectonic plates, which are themselves driven by the buoyancy-induced poloidal flow in the mantle. This surface coupling of poloidal and toroidal flows, due to the presence of surface tectonic plates, is discussed in the next section.

1.27.2.3.7 Incorporating tectonic plates as a surface boundary condition

The boundary conditions at the top of the mantle are more complex because of the presence of tectonic plates. If the plates are assumed to be an integral part of the underlying mantle flow and they fully participate in the flow, then a simple free-slip surface boundary condition would be appropriate. This free-slip assumption has often been employed in tomography-based flow studies (e.g., Forte and Peltier, 1987; Hager and Richards, 1989; Hager et al., 1985; King and Masters, 1992). If, on the other hand, we recognize that the plates are mechanically and rheologically distinct from the underlying mantle, then a more realistic surface boundary condition that explicitly treats the effective rigidity of plates is required.

Essentially, rigid tectonic plates are a fundamental aspect of convection dynamics in the Earth, and although their treatment lies beyond classical fluid mechanics theory, their dynamic impact on thermal convection in the mantle must be considered. One approach for modeling the coupling of convection and plates, developed by Ricard and Vigny (1989) and Gable et al. (1991), is based on an explicit treatment of the net vertical torque (or horizontal force) acting on the base of each surface plate. This method is a direct extension of the torque-balance analysis originally employed by Hager and O'Connell (1981) in their modeling of dynamic plate motions. The fundamental underlying assumption in the method developed by Ricard and Vigny is that the plate boundaries are completely stress-free. This method has been employed in a number of mantle flow models over the past few years (e.g., Corrieu et al., 1994; Lithgow-Bertelloni and Richards, 1998).

An alternative method for coupling the motions of rigid surface plates to buoyancy-induced mantle flow was developed by Forte and Peltier (1991, 1994). Only the main aspects of this method will be summarized here. It may be shown that for a given geometry of surface plates, the internal density anomalies $\rho_1(r, \theta, \phi)$ are partitioned into two families:

$$\rho_1(r, \theta, \phi) = \hat{\rho}_1(r, \theta, \phi) + \overline{\rho}_1(r, \theta, \phi) \qquad [90]$$

where the density perturbations $\hat{\rho}_1(r, \theta, \phi)$ are obtained through a projection operator $\hat{P}$ as follows:

$$\hat{\rho}_{1s}^{\,t}(r) = \hat{P}_{s,t,l,m}(r)\rho_{1l}^{\,m}(r) \qquad [91]$$

The calculation of the projection operator $\hat{P}_{s,t,l,m}(r)$ is given in Forte and Peltier (1994) and it depends on the geometry of the surface plates. The other component of the density anomalies $\overline{\rho}_1(r, \theta, \phi)$ is simply given by the expression

$$\overline{\rho}_{1s}^{\,t}(r) = \rho_{1s}^{\,t}(r) - \hat{\rho}_{1s}^{\,t}(r) \qquad [92]$$

As Forte and Peltier (1994) showed, the poloidal mantle flow field produced by the component $\hat{\rho}_1$ is consistent with the geometry of possible rigid plate motions at the surface, whereas the one produced by $\overline{\rho}_1$ is orthogonal to any possible plate motion. In other words, the plates participate in the underlying flow driven by $\hat{\rho}_1$, while they resist the flow produced by $\overline{\rho}_1$. Hence, free-slip $(T^p(r_s)=0)$ and no-slip $(V^p(r_s)=0)$ surface boundary conditions are applied to model the internal flows driven by $\hat{\rho}_1$ and $\overline{\rho}_1$, respectively.

A simple application of the plate projection operator is illustrated in Figure 7, where we compare the buoyancy-driven plate motions predicted on the basis of two hypothetical hot thermal anomalies under the Pacific Plate, which differ only in their spatial relationship to the nearby East Pacific Ridge (EPR). Both 'plumes' are constructed in an ad hoc manner as rectangular-shaped, negative density anomalies with constant amplitude $-0.1\ \mathrm{g\,cm^{-3}}$ located in the depth range 400–750 km, equivalent to -2.6% relative density perturbation at 525 km depth. This amplitude is much greater than expected on the basis of the seismic tomography models (see Figure 12) and is only used here for the purpose of illustration. The predicted mantle flow field varies linearly with the amplitude of the driving density anomaly; therefore, a 'plume' anomaly that is ten times smaller $(-0.01\ \mathrm{g\,cm^{-3}})$ will produce surface motions ten times smaller than those shown in Figure 7.

In the absence of plates, both of the hypothetical plumes (Figure 7(a) and 7(b)) produce the same amplitude and pattern of horizontal flow divergence at the surface of the mantle (compare Figure 7(c) with 7(d)). The situation changes radically when the present-day configuration of rigid plates is imposed at the top of the mantle. The plume that is offset from the nearest plate boundary (Figure 7(a)), the EPR, drives a mantle flow field, which produces only a small fraction of the horizontal surface divergence obtained in the absence of plates (compare Figure 7(c) with 7(e)). The plate projection operator [91] maps most of the original plume density anomaly ρ_1 into

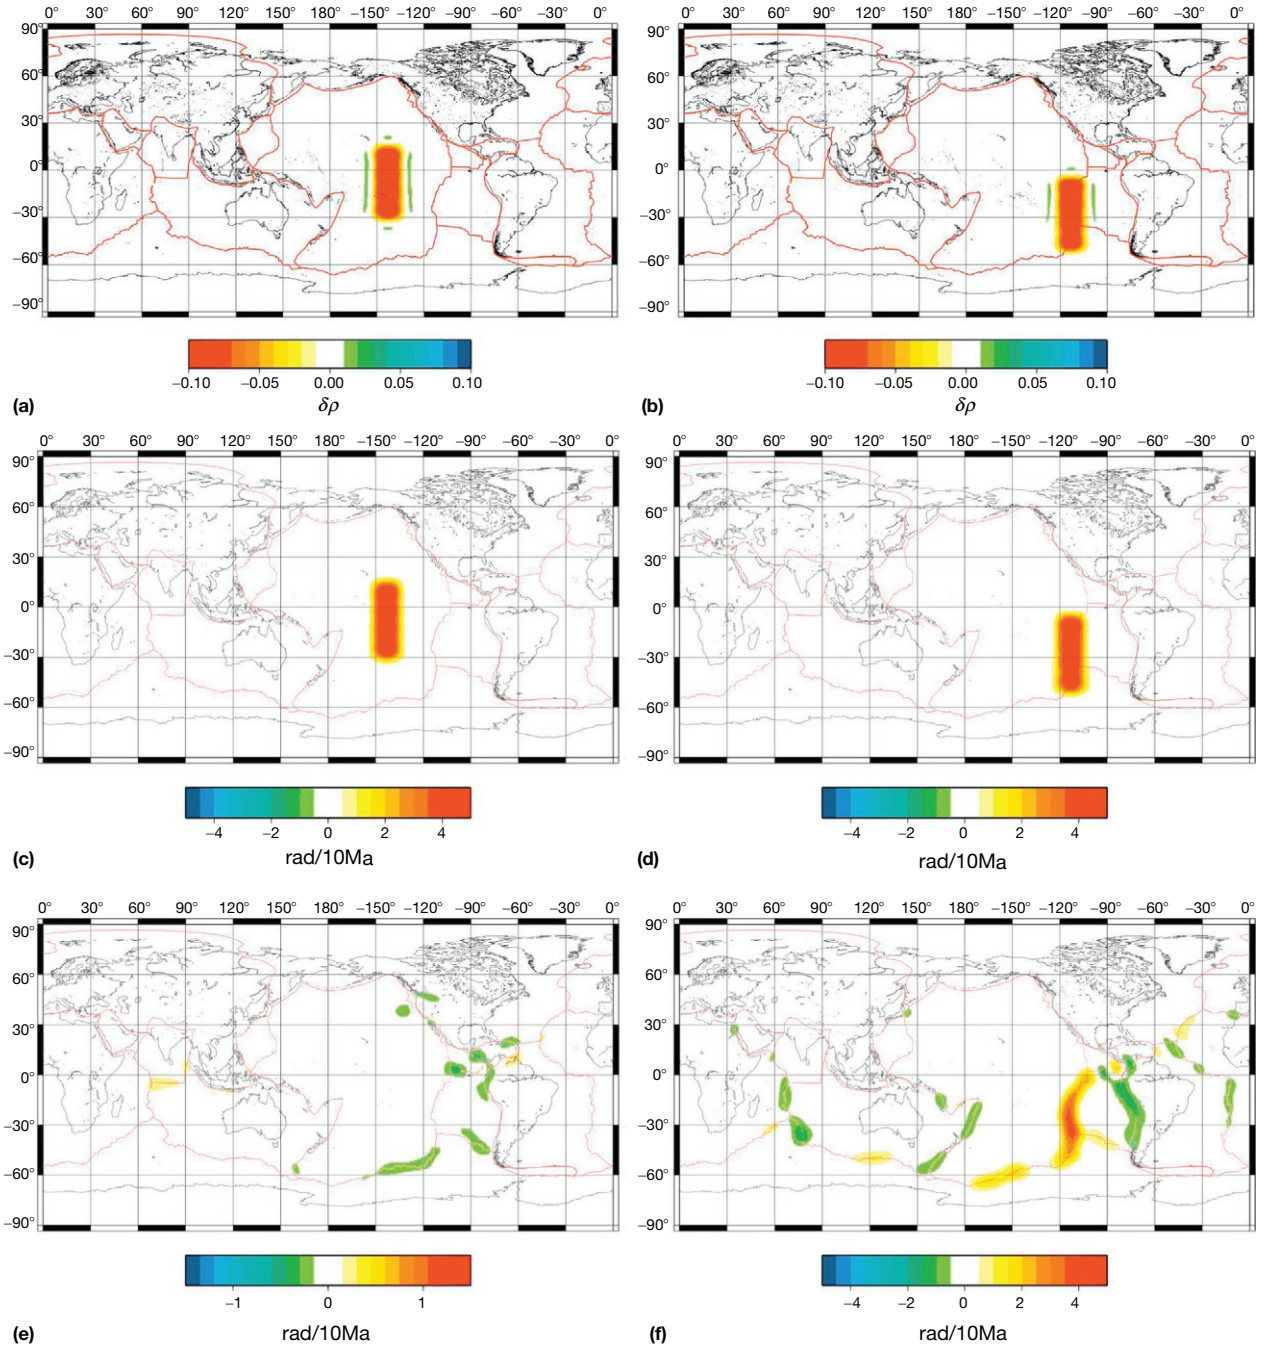

Figure 7 Interaction of hypothetical upwelling plumes with rigid surface plates. Maps (a) and (b) show two rectangular-shaped, negative density anomalies (the hypothetical 'plumes') with amplitude -0.1 g cm^{-3} assumed to be constant in the depth interval 400–750 km. Both plume anomalies have been expanded in terms of spherical harmonics up to degree and order 32. Maps (c) and (d) show the corresponding patterns of predicted horizontal surface divergence for a hypothetical mantle with a free-slip surface boundary (no plates) where the predicted motions are calculated up to harmonic degree 32. The mantle flow calculation was carried out assuming a depth-dependent viscosity variation shown in **Figure 9**. Maps (e) and (f) show the corresponding patterns of plate divergence (up to harmonic degree 32) when the present-day configuration of rigid tectonic plates is imposed as a surface boundary condition in the mantle flow calculation.

the no-slip family of density anomalies $\overline{\rho}_1$, which cannot produce observable plate motions. According to the alternative plate motion theory employed by Ricard and Vigny (1989), this hypothetical plume anomaly produces flow-induced driving torques on the overlying Pacific Plate, which nearly cancel because the center of the upwelling is too far away from the nearest plate boundary. In contrast, the plume located under the EPR (**Figure 7(b)**) produces horizontal divergence of the Pacific and Nazca Plates with an amplitude comparable with that obtained in the absence of plates (compare **Figure 7(d)**

with 7(f)). In this case, a substantial fraction of the original density anomaly ρ_1 was mapped into the free-slip family of density anomalies $\hat{\rho}_1$. It should be noted that mutual interactions among the plates will generate nonzero far-field plate divergence and convergence (Figure 7(f); e.g., in the Indian Ocean), which is a consequence of the assumed rigidity of the plates.

From the perspective of the tectonic plates, the existence of a null-space corresponding to the family of internal density anomalies $\hat{\rho}_1$ [92], which cannot drive observable motions (as in Figure 7(e)), constitutes a fundamental nonuniqueness in the interpretation of plate tectonics. The present-day plate motions (DeMets et al., 1990), or the geologic reconstructions of the history of plate motions (Gordon and Jurdy, 1986), therefore provide completely nonunique constraints on the mantle density anomalies generated by the thermal convection process. Other convection-related observables (e.g., global gravity anomalies) are required to constrain the density anomalies, which fall into the null-space $\hat{\rho}_1$. A further exploration of the implications of the nonunique interpretation of plate motions is presented by Forte and Peltier (1994).

The plate motions, which are driven by the buoyancy-induced (poloidal) mantle flow 30, will necessarily posses a toroidal component. This toroidal component is directly coupled to the poloidal component of the plate motions as follows:

$$(\hat{\mathbf{r}}\cdot\nabla\times\mathbf{v})_s^t = C_{s,t,l,m}(\nabla_H\cdot\mathbf{v})_l^m \qquad [93]$$

in which the spherical harmonic coefficients of the radial vorticity of the plate velocity field $\mathbf{v}$ are linearly dependent on the harmonic coefficients of the horizontal divergence of the plate motions. The vorticity and divergence fields are themselves directly dependent on the toroidal and poloidal scalar representations, respectively, of the plate velocity field (Forte and Peltier, 1987). It is important to note that expression [93] is only valid for toroidal harmonic degree $s \geq 2$ and that the coupling matrix $C_{s,t,l,m}$ is dependent only on the geometry of the plates (Forte and Peltier, 1994).

As discussed previously in Section 1.27.2.3.6, the viscous coupling between the plates and underlying mantle will result in the downward propagation of the surface toroidal flow into the mantle. The surface boundary condition [74] requires that the toroidal mantle flow match the toroidal component of plate motions, which is equivalent to their radial vorticity [93]:

$$V^T = U^T(a^-) = \frac{r_a}{\Omega_1}(\hat{\mathbf{r}}\cdot\nabla\times\mathbf{v})_l^m \qquad [94]$$

where $\imath = \sqrt{-1}$ and $r_a = a$ is the mean radius of the solid surface (6368 km).

The Green function solutions of the poloidal and toroidal-flow equations (see Section 1.27.2.3.6) may be used to describe the viscous response of the mantle to an arbitrary distribution of internal density anomalies ρ_1 as follows:

$$\begin{pmatrix} U_\ell^{\alpha m}(r) \\ T_\ell^{\alpha\beta m}(r) \end{pmatrix} = \int_b^a \begin{pmatrix} \mathsf{U}_\ell^{\alpha}(r,r') \\ \mathsf{T}_\ell^{\alpha\beta}(r,r') \end{pmatrix} \rho_1{}_\ell^m(r')\mathrm{d}r' \qquad [95]$$

where $U_\ell^{\alpha m}(r)$ and $T_\ell^{\alpha\beta m}(r)$ are the generalized spherical harmonic coefficients of the velocity and stress fields [31] and [32], respectively, and $\mathsf{U}_\ell^{\alpha}(r,r')$ and $\mathsf{T}_\ell^{\alpha\beta}(r,r')$ are the corresponding (poloidal) Green functions.

Tectonic plates may well represent the most extreme manifestation of lateral variations in rheology in the convecting mantle. The plate coupling procedure described earlier thus provides an explicit means of incorporating the dynamic impact of such extreme lateral heterogeneity in the flow calculations, which will be presented in the succeeding text. It is nonetheless true that eqns [35] and [36] governing flow in the mantle do not include lateral variations in viscosity and hence buoyancy forces will only directly excite a poloidal flow. In these calculations, toroidal mantle flow is excited passively from above, via the rotating surface plates.

A more general flow theory that models the effects of lateral viscosity variations (LVV) throughout the mantle (e.g., Forte and Peltier, 1994; Martinec et al., 1993) is required to describe the direct excitation of toroidal flow by mantle buoyancy forces. The dynamic implications of large-amplitude LVV throughout the mantle have been studied by Moucha et al. (2007). Despite the considerably more complex theory (relative to eqns [35] and [36]) needed to calculate flow in a 3-D viscosity field, Moucha et al. found the impact on predicted surface observables such as topography and geoid is relatively small. This finding provides important support for the modeling and interpretation of geodynamic observables using the plate-coupled flow theory with purely depth-dependent viscosity in the mantle. The results obtained on the basis of this simplified treatment of mantle dynamics will be presented in the sections that follow.

1.27.2.4 Geodynamic Response Functions for the Mantle

The theoretical relationship between the mantle density anomalies and the principal convection-related surface observables (i.e., geoid or gravity anomalies, dynamic surface and CMB topography, and plate motions) may be summarized in terms of geodynamic response or kernel functions (see Forte, 2000; Hager and Clayton, 1989, for reviews). These kernel functions are calculated in the spherical harmonic spectral domain using the viscous flow Green functions defined in expression [95]. The principal assumption we shall make in calculating these geodynamic kernels – in addition to the assumption of purely depth-dependent viscosity below the plates – is that the 670 km seismic discontinuity is not a barrier to radial mantle flow. This whole-mantle flow assumption has been recently subjected to a series of direct tests based on joint inversions of global seismic and geodynamic data sets (Simmons et al., 2006). It is found that the most satisfactory reconciliation of the global seismic and geodynamic constraints on 3-D mantle structure is obtained with whole-mantle flow and significantly poorer fits are obtained with flow models, which assume vertical flow barriers at 670 km depth or within the lower mantle (e.g., at 1800 km depth).

The geoid kernels $G_\ell(\eta; r)$ relate the spherical harmonic coefficients of the nonhydrostatic geoid field, δN_ℓ^m, to the spherical harmonic coefficients of the density perturbations $\delta\rho_\ell^m(r)$ as follows:

$$\delta N_\ell^m = \frac{3}{(2\ell+1)\overline{\rho}}\int_{r_{\mathrm{cmb}}}^{r_s} G_\ell(\eta; r)\delta\rho_\ell^m(r)\mathrm{d}r \qquad [96]$$

where $\overline{\rho} = 5.515\,\mathrm{Mg\,m^{-3}}$ is the mean density of the Earth, r_s is the mean radius of the solid surface, and r_{cmb} is the mean radius of the CMB. The geoid kernels are a functional of the nondimensional radial mantle viscosity profile $\eta(r)/\eta_o$. The free-air gravity anomaly coefficients δG_ℓ^m are related to the nonhydrostatic geoid coefficients δN_ℓ^m as follows:

$$\delta G_\ell^m = (\ell - 1)\frac{g_o}{R_o}\delta N_\ell^m \qquad [97]$$

where $g_o = 9.82\ \mathrm{m\ s^{-2}}$ (982 000 mGal) is the mean gravitational acceleration at Earth's surface and $R_o = 6371$ km is Earth's mean radius. Through the combination of eqns [96] and [97], we can relate the gravity anomaly coefficients to the internal density perturbations.

As discussed in the preceding section, a dynamic flow model that incorporates rigid plate motions must include mixed free-slip and no-slip surface boundary conditions. In the calculation of the flow-related observables, we must therefore determine the separate contributions provided by the density anomalies $\delta\hat{\rho}$ and $\delta\overline{\rho}$, which are convolved with kernel functions derived with free-slip and no-slip surface boundaries, respectively. For example, in the case of the nonhydrostatic geoid anomalies, we rewrite eqn [96] as follows:

$$\delta N_\ell^m = \frac{3}{(2\ell+1)\overline{\rho}}\int_{r_{cmb}}^{r_s}\left[\hat{G}_\ell(\eta; r)\delta\hat{\rho}_\ell^m(r) + \overline{G}_\ell(\eta; r)\delta\overline{\rho}_\ell^m(r)\right]\mathrm{d}r \qquad [98]$$

where the geoid kernels $\hat{G}_\ell(\eta; r)$ and $\overline{G}_\ell(\eta; r)$ are calculated with free-slip and no-slip surface boundaries, respectively. As shown in Forte and Peltier (1994), the density anomalies $\delta\hat{\rho}$ are spatially correlated with the positions of divergent or convergent plate boundaries. Subducting slabs and mid-ocean ridge heterogeneity are therefore resolved as part of the $\delta\hat{\rho}$ anomalies.

The surface topography kernel functions $T_\ell(\eta; r)$ relate the spherical harmonic coefficients of the flow-induced surface topography δa_ℓ^m to the spherical harmonic coefficients of the internal density anomalies as follows:

$$\delta a_\ell^m = \frac{1}{\Delta\rho_{mo}}\int_{r_{cmb}}^{r_s}\left[\hat{T}_\ell(\eta; r)\delta\hat{\rho}_\ell^m(r) + \overline{T}_\ell(\eta; r)\delta\overline{\rho}_\ell^m(r)\right]\mathrm{d}r \qquad [99]$$

where $\Delta\rho_{mo} = 2.2\ \mathrm{Mg\,m^{-3}}$ is the density jump across the mantle–ocean boundary and $\hat{T}_\ell(\eta; r)$ and $\overline{T}_\ell(\eta; r)$ are calculated with free-slip and no-slip surface boundaries, respectively.

Similarly, the spherical harmonic coefficients of the flow-induced CMB topography δb_ℓ^m may be expressed in terms of CMB topography kernels $B_\ell(\eta; r)$ as follows:

$$\delta b_\ell^m = \frac{1}{\Delta\rho_{cm}}\int_{r_{cmb}}^{r_s}\left[\hat{B}_\ell(\eta; r)\delta\hat{\rho}_\ell^m(r) + \overline{B}_\ell(\eta; r)\delta\overline{\rho}_\ell^m(r)\right]\mathrm{d}r \qquad [100]$$

where $\hat{B}_\ell(\eta; r)$ and $\overline{B}_\ell(\eta; r)$ are calculated with free-slip and no-slip surface boundaries, respectively, and $\Delta\rho_{cm} = -4.43\ \mathrm{Mg\,m^{-3}}$ is the density jump across the CMB. As in the case of the nonhydrostatic geoid in eqn [98], the dependence on viscosity of the predicted surface and CMB topography appears explicitly through the nondimensional profile $\eta(r)/\eta_o$.

Surface plate velocities $\mathbf{v}$ may be characterized by their horizontal divergence field $\nabla_H\cdot\mathbf{v}$ (Forte and Peltier, 1987). The horizontal divergence kernels $D_\ell(\eta; r)$ relate the spherical harmonic coefficients of the predicted plate divergence $(\nabla_H\cdot\mathbf{v})_\ell^m$ to the spherical harmonic coefficients of the density perturbations as follows:

$$(\nabla_H\cdot\mathbf{v})_\ell^m = \frac{g_o}{\eta_o}\int_{r_{cmb}}^{r_s} D_\ell(\eta; r)\delta\hat{\rho}_\ell^m(r)\mathrm{d}r \qquad [101]$$

in which the free-slip component of the mantle density anomalies $\delta\hat{\rho}$, defined in expression [91], is required to model the surface divergence of the plates. We also note the presence of the reference scaling value of viscosity η_o. This presence implies that plate motions, unlike the other observables in eqns [96]–[100], will be dependent on the absolute value of mantle viscosity.

1.27.2.5 Depth Dependence of Mantle Viscosity

Understanding the long timescale rheology of the mantle as represented by its effective viscosity is a central and enduring problem in global geophysics. The diverse methods and data sets that have been employed to constrain mantle viscosity have been a source of ongoing contention and debate. The importance and intensity of this debate are an apt reflection of the fundamental role of mantle viscosity in controlling a wide array of geodynamic processes. For example, millennial timescale glacial isostatic adjustment (GIA) processes such as Pleistocene and Holocene sea-level variations and related anomalies in Earth's gravitational field and rotational state are known to be strongly dependent on the depth dependence of mantle viscosity. On much longer, million- to hundred million-year timescales, viscosity exerts fundamental control on the dynamics of mantle convection and on the corresponding evolution of the thermal and chemical state of Earth's interior. The very long timescale implications of mantle viscosity also include fundamental surface geologic and geophysical processes, such as global-scale epeirogeny and associated sea-level changes, global geoid anomalies, and tectonic plate motions.

The spatial variation of viscosity in Earth's mantle can, in principle, be determined from a consideration of the microphysical properties, which control the steady-state creep of mantle rocks (e.g., Nicolas and Poirier, 1976; Sammis et al., 1977). In practice, however, the microphysical models of mantle viscosity depend on knowledge of a number of critical physical properties, such as grain size and activation volume and energy, which are poorly known in the mantle and hence require extrapolations of laboratory creep experiments, which greatly exceed the physical conditions (i.e., pressure, temperature, or creep rate) under which these experiments were originally performed. It is nonetheless possible to show, on the basis of microphysical considerations, that the global horizontal average viscosity may increase by up to three orders of magnitude across the mantle (e.g., Ranalli, 2001). More precise determinations of the radial viscosity profile require additional constraints from geophysical data sets, which are sensitive to the long-term rheology of the mantle.

The first and most influential geophysical contribution to our understanding of mantle viscosity is Haskell's (1935) study of Fennoscandian postglacial uplift, which was found to require an average viscosity of 10^{21} Pa s down to a depth approximately equal to the horizontal dimension of the surface load (about

1000–1500 km). McConnell's (1968) spectral analysis of the Fennoscandian uplift data led to the inference that mantle viscosity increased significantly with depth while at the same time still satisfying the Haskell average. The Haskell average value of viscosity over the upper 1000–1200 km of the mantle was also supported in subsequent work by O'Connell (1971). These initial studies that supported the compatibility between the Haskell constraint on viscosity and significant increases of viscosity in the lower mantle were displaced by subsequent analyses by Cathles (1975) and Peltier and Andrews (1976) who concluded that viscosity was nearly constant from the base of the lithosphere to the CMB. This view of mantle viscosity characterized by only moderate increases with depth was reinforced in later studies involving larger GIA data sets (e.g., Tushingham and Peltier, 1991; Wu and Peltier, 1983). A review of the GIA constraints on viscosity may be found in Mitrovica (1996).

The first inferences of the depth variation of mantle viscosity based on surface data sets associated with mantle convection (e.g., Hager, 1984; Richards and Hager, 1984; Ricard et al., 1984) disagreed strongly with the GIA inferences of mantle viscosity, which prevailed since the earliest studies by Cathles, Peltier, and collaborators. These convection-based analyses of viscosity, in particular the first study of Earth's global geoid anomalies by Hager (1984), suggested a large increase of viscosity in the sublithospheric mantle with an approximately factor of 30 increase in the average viscosity of the lower mantle relative to the upper mantle. This conclusion was supported by subsequent studies by Forte and Peltier (1987) and Forte et al. (1991) who extended the viscous flow modeling to include the plate velocities. The geodynamic inferences for significant (one to two orders of magnitude) increases in the average viscosity of the lower mantle relative to that of the upper mantle were reinforced by subsequent analyses carried out by Ricard et al. (1989), Ricard and Vigny (1989), Hager and Clayton (1989), Forte and Peltier (1991), Forte et al. (1993a, 1994), King and Masters (1992), Corrieu et al. (1994), and Thoraval and Richards (1997). A survey of some of the earliest viscosity inferences derived on the basis of global geoid anomalies is shown in **Figure 8**. Reviews of mantle viscosity inferences based on either convective flow or GIA data sets may be found in King (1995) and Kaufmann and Lambeck (2000).

Additional geodynamic considerations that suggest a substantial increase of viscosity with depth are based on a wide variety of analyses, which include the stability of the hot spot reference frame (e.g., Quéré and Forte, 2006; Richards, 1991), long-term rates of polar wander (e.g., Richards et al., 1997; Sabadini and Yuen, 1989; Spada et al., 1992; Steinberger and O'Connell, 1997), and the planform of mantle convection (e.g., Bunge et al., 1996; Forte and Mitrovica, 2001; Zhang and Yuen, 1995).

The inference of mantle viscosity from convection-related surface data, considered in the context of tomography-based mantle flow models, was initially carried out through an effectively trail-and-error fitting procedure (e.g., Forte and Peltier, 1987, 1991; Forte et al., 1993a,b,c; Hager and Clayton, 1989). Subsequently, a number of formal mathematical inversions of the geodynamic data were carried out (e.g., Corrieu et al., 1994; Forte, 2000; Forte and Mitrovica, 1996; Forte et al., 1991; Kido et al., 1998; King, 1995; King and Masters, 1992; Panasyuk and Hager, 2000; Ricard and Wuming, 1991). The viscosity profiles obtained by inverting geodynamic data sets (**Figure 8**) are all characterized by strong overall increases in viscosity with depth, but it is also clear that there are significant differences in the detailed character of these viscosity inferences. There are many factors that can contribute to these differences and they include, most notably, the use of different tomography-based inferences of mantle density anomalies, different combinations of geodynamic data (e.g., geoid only, geoid plus plate motions, geoid plus dynamic topography, and all of the preceding texts), and different inversion methods (e.g., Monte Carlo, Bayesian, genetic, and Occam algorithms). The formulation of the viscous flow models themselves can also play a critical role in explaining these differences, since it is known that the use of different surface boundary conditions (e.g., free-slip, no-slip, and freely rotating tectonic plates) will lead to rather different viscosity inferences (e.g., Thoraval and Richards, 1997). Finally, the limited resolving power of the geodynamic constraints precludes a direct interpretation of viscosity at any given depth in the mantle. For example, Forte and Mitrovica (2001) found that the combined constraints provided by global free-air gravity anomalies, tectonic plate motions, and excess ellipticity of the CMB could only resolve average values of viscosity in rather broad depth intervals.

The discordant viscosity inferences derived from either GIA or convection-related data sets were initially regarded as evidence for the transient nature of mantle viscosity over the timescales that separate these two processes (e.g., Peltier, 1985; Sabadini et al., 1985). The necessity for time-dependent viscosity in the mantle was later weakened by two independent analyses of the GIA data sets. The first argument against transient viscosity was provided by an analysis of differential Late Holocene sea-level high stands in the Australian region by Nakada and Lambeck (1989), who showed that these GIA data required a nearly two orders of magnitude increase of viscosity across the mantle. The second independent argument was provided by Mitrovica (1996), who showed that previous inferences of a nearly constant-viscosity mantle (e.g., Tushingham and Peltier, 1991; Wu and Peltier, 1983) were conditioned by a misinterpretation of the original Haskell (1935) constraint. The latter was erroneously assumed to apply only to the top 670 km of the mantle (i.e., the upper mantle), rather than to the average value of viscosity down to depths of about 1000–1500 km (Mitrovica, 1996).

The recognition that GIA data are not incompatible with large increases of mantle viscosity with depth spurred new efforts to reconcile GIA and convection data sets with a single profile of mantle viscosity. The first efforts were undertaken by Forte and Mitrovica (1996) and Mitrovica and Forte (1997). Despite the very different timescales and spatial scales over which these processes operate, these authors found that it was possible to simultaneously explain both decay times associated with the postglacial uplift of Hudson Bay and Fennoscandia and long-wavelength free-air gravity anomalies associated with mantle convection with a single viscosity profile characterized by an approximately two orders of magnitude increase with depth, which also satisfied the original Haskell constraint on mantle viscosity. These joint GIA–convection inversions culminated in the recent study by Mitrovica and Forte (2004) in which the

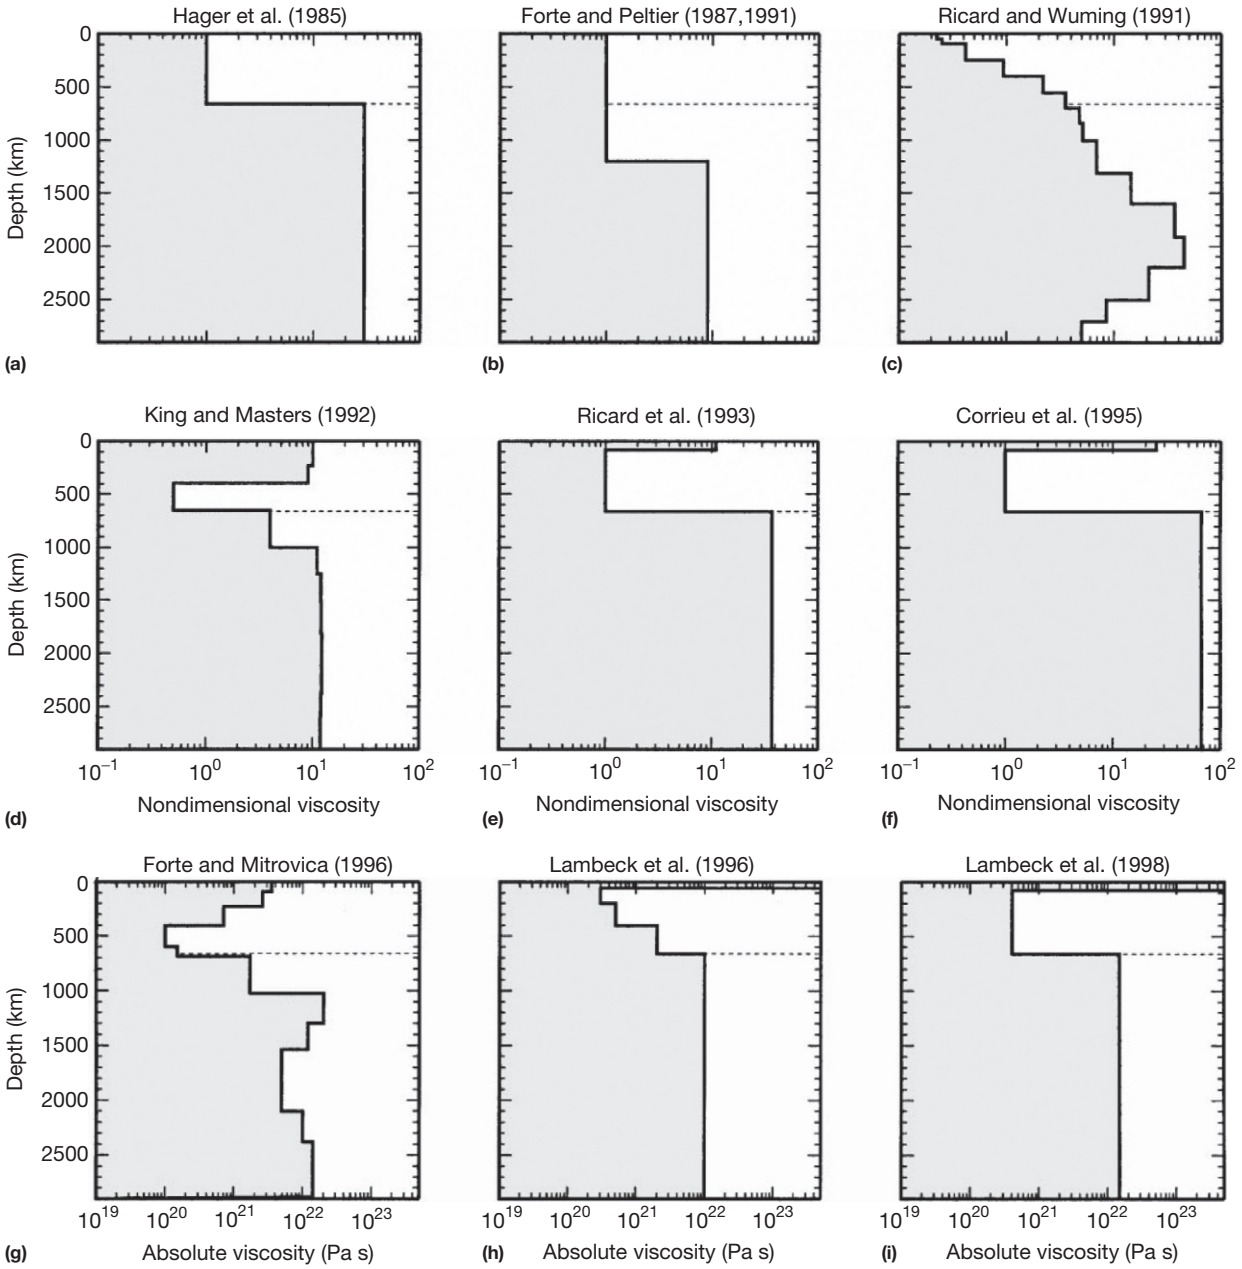

Figure 8 A survey of previous geodynamic inferences of depth-dependent mantle viscosity. Frames (a)–(f) show relative (nondimensional) variations of viscosity with depth derived on the basis of global long-wavelength geoid anomalies. Frames (g)–(i) show radial (absolute) viscosity profiles inferred on the basis of GIA data (in addition to geoid data in the case of frame (g)). The GIA data sets constrain the absolute value of viscosity, whereas the steady-state viscous flow modeling of the geoid data only constrains relative variations of viscosity with depth. Adapted from Kaufmann G and Lambeck K (2000) Mantle dynamics, postglacial rebound and the radial viscosity profile. *Physics of the Earth and Planetary Interiors* 121: 301–324.

range of viscosity profiles consistent with both families of surface data is summarized in Figure reffig-visc. The convection data employed in these viscosity inversions are shown in Figure 2. The GIA data include the Fennoscandian relaxation spectrum and a set of decay times determined from the postglacial sea-level history in Hudson Bay and Sweden.

The inverted viscosity profiles are characterized by a three orders of magnitude increase from the upper mantle (mean value of $\sim 4 \times 10^{20}$ Pa s) to a high-viscosity ($> 10^{23}$ Pa s) peak at 2000 km depth. Below 2000 km, the viscosity shows a significant, two to three orders of magnitude, reduction toward the CMB. Similar radial variations in lower-mantle viscosity have been inferred in other independent studies (e.g., Ricard and Wuming, 1991). The preferred viscosity profile (solid black line, Figure 9) provides an optimal fit to both (GIA and convection) families of data, and unless stated otherwise, this profile will be employed to calculate all convection-related surface observables presented in the succeeding text.

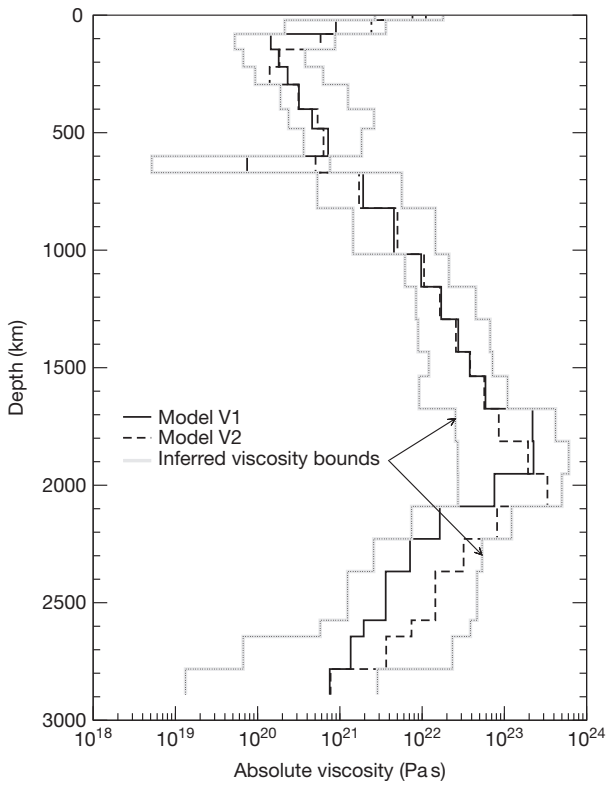

Figure 9 Results of inversions of the GIA and convection data sets. Full details of the inversions are presented in Mitrovica and Forte (2004). The convection data are interpreted in terms of a tomography-based mantle flow model in which the density anomalies are derived from the Grand (2002) tomography model (**Figure 3(b)**). The thick gray lines illustrate the range of allowable values of mantle viscosity, which are consistent with the joint GIA–convection constraints. The solid black line (model V1) is the preferred viscosity profile, on the basis of the Grand (2002) tomography model, which provides an optimal fit to the entire suite of geodynamic data. The dashed line (model V2) was inverted with strong smoothing constraints applied across the horizon separating upper and lower mantle and yields slightly lower fits to the combined GIA–convection data sets (Forte et al., 2010).

The geodynamic response or kernel functions calculated on the basis of the preferred mantle viscosity profile (model 'V1' in **Figure 9**) are illustrated in **Figure 10**. Comparing the free-slip and no-slip geoid kernels, we note that the largest contribution from density anomalies in the top half of the mantle is provided by those anomalies $\delta\hat{\rho}$ that are efficient in driving observable plate motions. These anomalies correspond to subducting slabs and upper-mantle plumes below the mid-ocean ridges. In the bottom half of the mantle, the density anomalies belonging to the $\delta\overline{\rho}$ family provide the largest contribution to the surface geoid or gravity anomalies. These $\delta\overline{\rho}$ anomalies produce no observable plate motions. At sufficiently short horizontal wavelengths (corresponding to harmonic degrees $\ell \geq 32$), we note that the distinction between $\delta\hat{\rho}$ and $\delta\overline{\rho}$ anomalies begins to disappear: both provide equal contributions to the surface geoid or gravity anomalies. The free-slip and no-slip surface topography kernels show that the density anomalies $\delta\overline{\rho}$ provide the strongest contribution to dynamic surface topography, especially at long horizontal wavelengths (corresponding to the degree range $\ell = 2-8$). At short horizontal wavelengths, the distinction between the two classes of density anomalies again ceases to be important.

1.27.3 Modeling Geodynamic Observables with Seismic Tomography

We will now consider the extent to which the 3-D mantle structure resolved in recent seismic tomographic models may be used to explain the global convection-related data sets shown in **Figure 2**. The geodynamic response functions obtained on the basis of the preferred radial viscosity profile (**Figure 10**) will be used to establish the connection between the seismically inferred heterogeneity in the mantle and the surface geodynamic observables. A broad selection of seismic shear-velocity models, obtained in independent studies using diverse and complementary seismic data and using different seismic modeling and inversion techniques, will be employed here. Seismic shear-velocity heterogeneity is the initial focus of this tomography-based modeling because it is expected that S-wave anomalies δV_S will be most sensitive to the temperature anomalies maintained by the mantle convection process (e.g., Forte and Perry, 2000; Forte et al., 2002; Röhm et al., 2000).

1.27.3.1 Seismic Heterogeneity Models

The S-wave tomography models employed here are, in chronological order, model *S20A* (isotropic version) from Ekström and Dziewonski (1998), model *S20RTS* from Ritsema et al. (1999), model *SAW24* from Mégnin and Romanowicz (2000), model *SB4_L18* from Masters et al. (2000), model *TX2002* from Grand (2002), and model *J362D28* from Antolik et al. (2003). The spatial variation of seismic heterogeneity in these S-wave models is parameterized in terms of a wide assortment of basis functions, ranging from B-splines to piecewise-discontinuous layers in the radial direction and spherical harmonics to equal-area cells in the horizontal direction.

To facilitate a direct comparison among these seismic heterogeneity models and the subsequent usage of the models in viscous flow calculations, all models have been projected onto a common set of radial and horizontal basis functions as follows:

$$\frac{\delta V_S}{V_S} = \sum_{k=0}^{32} \sum_{\ell=0}^{20} \sum_{m=-\ell}^{+\ell} {}_k c_\ell^m T_k(x) Y_\ell^m(\theta, \varphi) \qquad [102]$$

in which $T_k(x)$ are Chebyshev polynomials in the normalized radius $x = (2r - r_{sur\,f} - r_{cmb})/(r_{sur\,f} - r_{cmb})$ and Y_ℓ^m are ordinary spherical harmonics. Notice that all models are expanded up to order 32 in the radial Chebyshev polynomials and up to degree 20 in the surface spherical harmonics.

When each of the S-wave heterogeneity models is projected onto the representation [102], the depth variations of the root-mean-square (rms) amplitudes of the velocity anomalies are shown in **Figure 11**. Here, we note that, with the exception of the top 300 km in the mantle, the average amplitudes of the relative perturbations of seismic shear velocity $\delta V_S/V_S$ show significant differences in the mantle, especially in the transition zone region (400–1000 km depth) and at the base of the mantle (2500–2891 km depth).

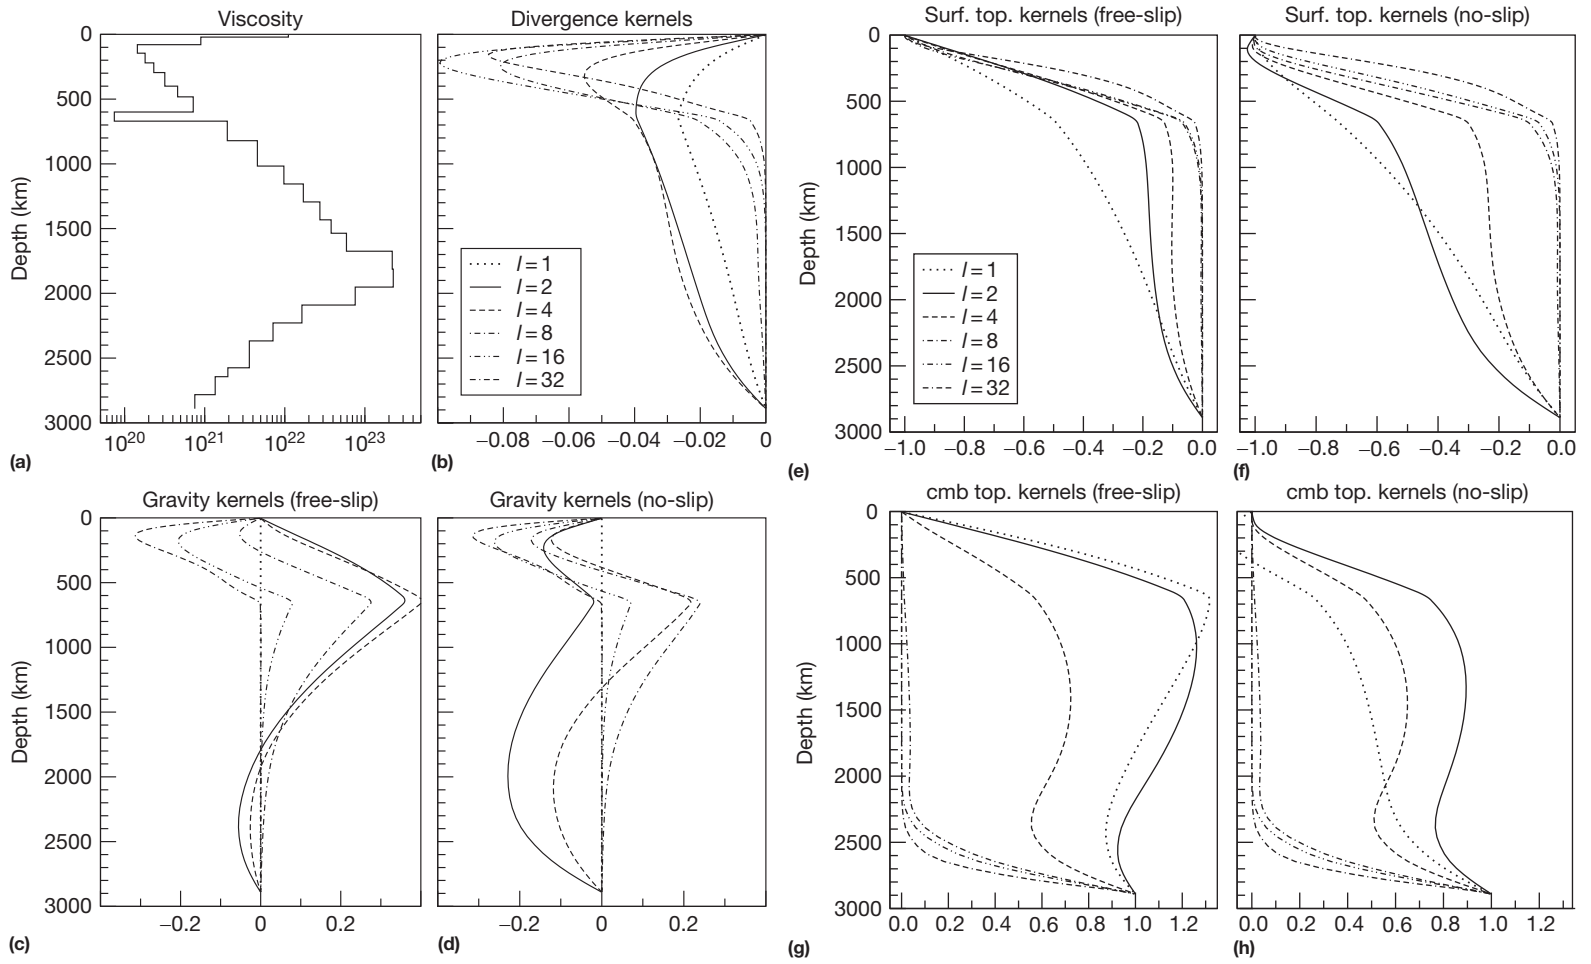

Figure 10 Geodynamic kernel functions. The geodynamic response functions shown here are calculated on the basis of the preferred GIA–convection-inferred viscosity profile shown in frame (a) (same as model 'V1' in **Figure 9**). The kernels corresponding to harmonic degrees $\ell = 1, 2, 4, 8, 16, 32$ are identified by the legend in frame (b) (repeated in frame (e)). The horizontal divergence kernels, defined in eqn [101], are shown in frame (b). The gravity kernels, defined in eqn [98], for free-slip and no-slip surface boundary conditions are shown in frames (c) and (d), respectively. The surface topography kernels, defined in eqn [99], for free-slip and no-slip conditions are shown in frames (e) and (f), respectively. The kernels for the dynamic CMB topography, defined in eqn [100], are shown in frame (g) and (h) for free-slip and no-slip conditions, respectively.

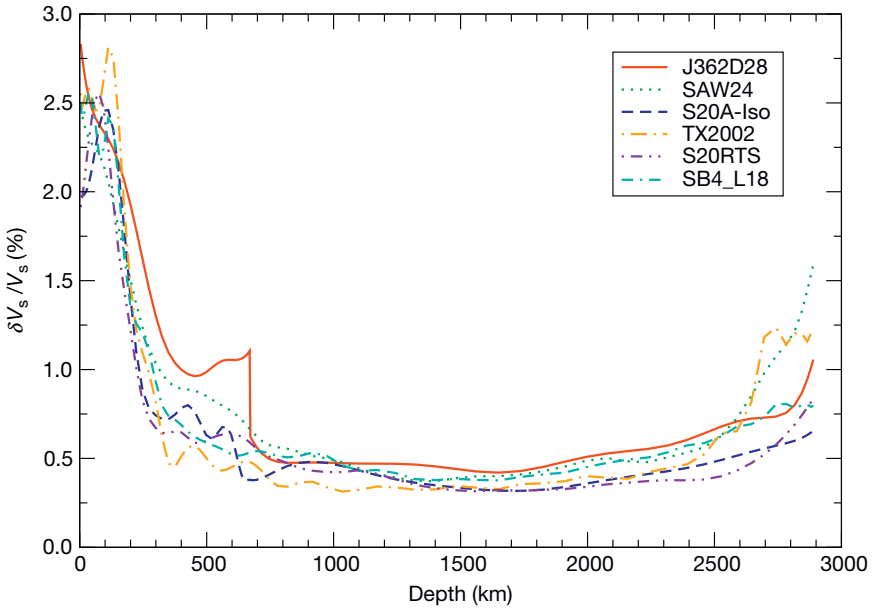

Figure 11 Amplitude of S-wave heterogeneity in the mantle. Plotted here is the root-mean-square (rms) amplitude of relative perturbations of seismic shear velocity obtained from the following tomography models: *J362D28* (Antolik et al., 2003), *SAW24* (Mégnin and Romanowicz, 2000), *S20A-Iso* (Ekström and Dziewonski, 1998), *TX2002* (Grand, 2002), *S20RTS* (Ritsema et al., 1999), and *SB4_L18* (Masters et al., 2000). All tomography models have been projected onto the spatial parameterization given by expression [102].

1.27.3.2 Mantle Density Anomalies

The mantle density anomalies required in modeling the convection-related surface observables may be derived from the seismic tomography models using experimental and theoretical results from mineral physics (e.g., Čadek et al., 1994; Jackson, 2001; Karato, 1993; Karato and Karki, 2001; Oganov et al., 2001a,b; Sobolev et al., 1997; Stacey, 1998; Stixrude and Lithgow-Bertelloni, 2001; Trampert et al., 2001; Wang and Weidner, 1996; Zhang and Weidner, 1999). This derivation would, however, require that the amplitudes of seismic velocity anomalies are well constrained and that all relevant mineralogical variables in the mantle (e.g., reference composition, temperature, and equation of state parameters) are sufficiently well known. To satisfy all these requirements at the same time is a great challenge, but efforts to simultaneously interpret mantle density and seismic velocity anomalies using mineral physics data are showing much promise (e.g., Forte and Woodward, 1997b; Forte et al., 1994; Simmons et al., 2007, 2009, 2010).

An alternative method for inferring mantle density anomalies is based on the direct inversion of the convection-related geophysical observables (e.g., Corrieu et al., 1994; Deschamps et al., 2001; Forte and Mitrovica, 2001; Forte and Perry, 2000; Forte et al., 1993a,b; Karpychev and Fleitout, 2000; Panasyuk and Hager, 2000; Pari, 2001). This approach is useful when contending with significant uncertainties in the amplitudes of the seismic anomalies, as is evident in **Figure 11**. This figure underscores a key concern, namely, that the use of mineral physics data to translate the seismic anomalies can lead to large variations in the estimated mantle density anomalies, depending on the choice of tomography model. To avoid this difficulty, it is preferable to carry out simultaneous inversions of all global geodynamic data (**Figure 2**) to determine an optimal velocity-to-density scaling factor $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ (e.g., Forte and Mitrovica, 2001), such that

$$\frac{\delta\rho}{\rho} = \left(\frac{\mathrm{d}\ln\rho}{\mathrm{d}\ln V_S}\right)\frac{\delta V_S}{V_S} \qquad [103]$$

where $\delta V_S/V_S$ are shear-velocity anomalies obtained from a tomography model and $\delta\rho/\rho$ are the relative perturbations in density, which are constrained by the geodynamic data. This approach has also been employed in other tomography-based mantle flow models (e.g., Corrieu et al., 1994; Hager and Clayton, 1989; Panasyuk and Hager, 2000).

The geodynamic data provide direct, linear constraints on the density anomalies in the mantle (see eqns [98]–[100]), which may be generically expressed as follows:

$$\begin{aligned}\delta O_\ell^m &= f_\ell \int_b^a K_\ell(\eta; r')(\rho_1)_\ell^m(r')\mathrm{d}r' \\ &\approx f_\ell \sum_{i=1}^{N} K_\ell(\eta; r_i)(\rho_1)_\ell^m(r_i)w_i \end{aligned} \qquad [104]$$

in which δO_ℓ^m are the spherical harmonic coefficients of a geodynamic observable (e.g., geoid or free-air gravity anomalies), $K_\ell(\eta; r')$ is the corresponding kernel function, and f_ℓ is a factor that depends on the geodynamic observable (see, e.g., eqn [98]). The numerical calculation of integrals is usually carried out with equivalent finite sums, such as in [104], where w_i is a weighting term, which depends on the numerical summation algorithm (e.g., Gauss–Legendre quadrature). On the basis of expression [103], we may further rewrite eqn [104] as

$$\delta O_\ell^m = f_\ell \sum_{i=1}^{N} w_i K_\ell(\eta; r_i)\rho_o(r_i)\left(\frac{\delta V_S}{V_S}\right)_\ell^m(r_i)\left(\frac{\mathrm{d}\ln\rho}{\mathrm{d}\ln V_S}\right)(r_i) \qquad [105]$$

in which $\delta V_S/V_S$ are the shear-velocity anomalies in the mantle and $d \ln \rho / d \ln V_S$ is the corresponding velocity-to-density scaling, which is assumed to vary with depth in the mantle.

Expression [105] provides the basis for a discrete, linear inversion of the geodynamic data δO_ℓ^m to find an optimal velocity-to-density scaling profile $d \ln \rho / d \ln V_S$. A series of Occam inversions (Constable et al., 1987) of the geodynamic data (**Figure 2**) were carried out to find the smoothest family of $d \ln \rho / d \ln V_S$ profiles, which are consistent with the data. For each Occam inversion, a different seismic shear wave tomography model (**Figure 11**) was employed, and in each case, the same geodynamic kernel functions (**Figure 10**) were employed to relate the mantle heterogeneity to the geodynamic data. The results of these inversions are summarized in **Figure 12**, which shows the optimal profiles of $d \ln \rho / d \ln V_S$ and the resulting depth variation of the rms amplitude of the lateral density anomalies implied by expression [103].

Mineral physics estimates of the velocity-to-density scaling (**Figure 12**) show significant departures from the scaling profiles derived from the Occam inversions. As discussed earlier, this discrepancy may in part arise from the inadequate resolution of seismic heterogeneity in the mantle – especially in the midmantle region between 1000 and 2000 km depth – and it may also arise from inadequacy of the theoretical assumptions inherent in the mineral physics estimates. In the latter case, the chief assumption that may be deficient is the dominance of thermal effects on both the seismic and density anomalies in the mantle. Compositional effects, especially on mantle density heterogeneity, may be one important explanation for the deviations from theoretical mineral physics estimates based on temperature effects alone (e.g., Stacey, 1998). The relative importance of thermal and compositional contributions to mantle heterogeneity can be directly tested in the context of simultaneous inversions of seismic and geodynamic data (Simmons et al., 2007, 2009, 2010), and these will be discussed in the succeeding text.

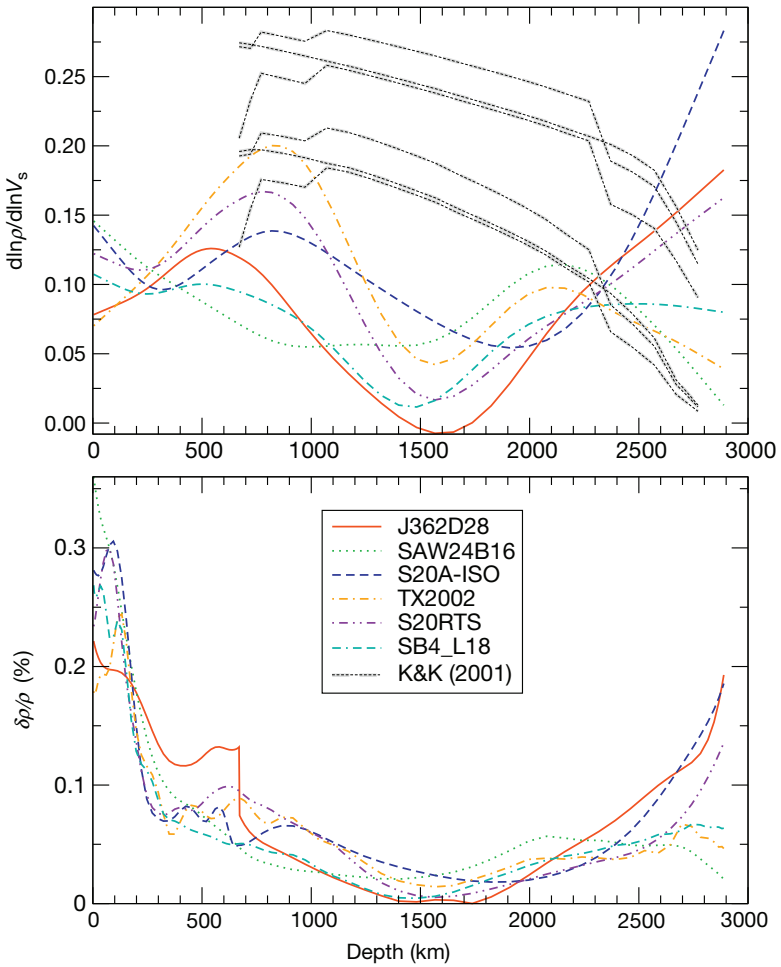

Figure 12 Occam inversions for mantle density anomalies. In the *top frame* are shown the optimal Occam-inferred velocity-to-density scaling profiles for each of the tomography models illustrated in **Figure 11**. The legend identifying the results is in the bottom frame. For comparison are shown (thick dashed gray lines) a series of theoretical estimates of the depth variation of $d \ln \rho / d \ln V_S$ in the lower mantle obtained by Karato and Karki (2001) on the basis of mineral physics data. These mineral physical estimates assume that both density and seismic anomalies are produced by temperature perturbations in the mantle. In the *bottom frame* are shown the resulting inferences of the depth variation of the rms density anomalies, which are calculated on the basis of the seismic shear-velocity anomalies using expression [103].

1.27.3.3 Predicted Tectonic Plate Motions

In this and the next few sections, we will consider the extent to which the tomography-based inferences of mantle density anomalies presented in Figure 12 provide a successful explanation of the convection-related surface observables (Figure 2). We begin here with a consideration of convection-induced tectonic plate motions. The predicted horizontal divergence of the plate motions, calculated on the basis of expression [101] and using the kernels in Figure 10(b), is presented in Figure 13 alongside the observed NUVEL-1 divergence of the plates. A detailed spectral comparison between the predicted and observed plate divergences is shown in Figure 14.

A quantitative summary of the overall agreement between the predicted and observed plate divergence, quantified in terms of total rms amplitude, total spatial correlation, and variance reduction, is provided in Table 1. The variance reduction is defined as follows:

$$\text{var.red.} = 100\% \times \left[1 - \frac{\sum_{\ell}\sum_{m=-\ell}^{+\ell}(O-P)_{\ell}^{m*}(O-P)_{\ell}^{m}}{\sum_{\ell}\sum_{m=-\ell}^{+\ell}O_{\ell}^{m*}O_{\ell}^{m}}\right] \quad [106]$$

where $(O-P)_{\ell}^{m}$ and O_{ℓ}^{m} are the harmonic coefficients of the difference between the observed and predicted fields and the observed fields, respectively.

An important characteristic of the predicted divergence fields shown in Figure 13, which is also confirmed in Table 1, is the subdued amplitude of the predicted fields relative to the data. As will be seen in the next few sections, all tomography-based predictions of geodynamic observables, which are calculated on the basis of the optimal Occam-inverted density-to-velocity scaling profiles (Figure 12), are systematically reduced in amplitude relative to the amplitude of the observed fields. This systematic bias to low predicted amplitudes is a natural consequence of the least-squares misfit criterion, which is employed in almost all inversion algorithms (including the Occam approach), which leads to significantly damped inferences of the $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ scaling profiles.

It can be readily shown that the inherent damping of tomography-based inferences of $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ arises as a consequence of poorly resolved 3-D seismic structure in geodynamically important regions of the mantle, such as the midmantle region (e.g., Forte et al., 1994). We can illustrate this in an inverse problem in which we seek, for the sake of simplicity, the best-fitting constant $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ value. As shown in expression [104], the predicted convection-related observables are linearly dependent on the internal density perturbations in the mantle. By virtue of expression [105], we may write

$$d(\theta,\varphi) = \left(\frac{\mathrm{d}\ln\rho}{\mathrm{d}\ln V_S}\right) p(\theta,\varphi)$$

where $d(\theta, \phi)$ represent the surface data and $p(\theta, \phi)$ is the corresponding mantle flow prediction assuming $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S = 1$. We can then show that the optimal $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ value that minimizes the least-squares misfit between data and the predictions is given by the following expression:

$$\frac{\mathrm{d}\ln\rho}{\mathrm{d}\ln V_S} = \frac{\sigma_d}{\sigma_p}\, c(d,p), \quad [107]$$

where σ_d and σ_p are the rms amplitudes of the data and the predictions,

$$\sigma_d^2 = \frac{1}{4\pi}\int\int_{S_1} |d(\theta,\varphi)|^2 d^2S, \;\; \sigma_p^2 = \frac{1}{4\pi}\int\int_{S_1} |p(\theta,\varphi)|^2 d^2S,$$

and

$$c(d,p) = \frac{1}{4\pi}\int\int_{S_1} d(\theta,\varphi)p(\theta,\varphi)\, d^2S \quad [108]$$

where all integrals are defined over the surface of the unit sphere S_1. The quantity $c(d, p)$ defined in [108] is the cross correlation between the data and the predictions. Equation [107] thus shows that the inferences of $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ will be directly proportional to the spatial correlation between the surface data and the corresponding geodynamic integral of the 3-D structure in the seismic tomography model. As previously shown by Forte et al. (1994), this correlation may be significantly degraded if the 3-D seismic structure is poorly resolved.

1.27.3.4 Predicted Free-Air Gravity Anomalies

Tomography-based mantle flow models of Earth's nonhydrostatic gravitational potential have almost exclusively been based on analyses of the equivalent geoid anomalies, beginning with the earliest studies by Richards and Hager (1984) and Hager et al. (1985) and continuing to recent studies (e.g., Panasyuk and Hager, 2000). Since the global geoid anomalies are strongly dominated by horizontal wavelengths corresponding to harmonic degrees $\ell = 2, 3$, they will effectively constrain only the longest wavelength components of 3-D mantle structure. To avoid this very long-wavelength bias, we consider here a representation of the nonhydrostatic geopotential in terms of equivalent global free-air gravity anomalies (see expression [97]). The free-air gravity anomalies contain a more evenly balanced representation of the different horizontal wavelengths in the nonhydrostatic geopotential (i.e., a 'flatter' amplitude spectrum).

The observed and predicted gravity anomaly fields, calculated on the basis of expressions [97] and [98] and using the kernels in Figure 10(c) and 10(d), are presented in Figure 15. A comparison of the predicted and observed gravity anomalies in the spectral domain is shown in Figure 16. In Table 2 is presented a detailed summary of the global agreement between the predicted and observed gravity anomalies. In contrast to the predicted plate divergence discussed in the preceding section, we note that the amplitudes of the predicted gravity anomaly fields are somewhat less muted (compare Tables 1 and 2). The overall agreement with the gravity data (in terms of variance reduction) is however poorer than the plate divergence fits because of the decreased spatial correlation between the predictions and the data.

1.27.3.5 Predicted Dynamic Surface Topography

The term 'dynamic topography' is here defined to include all contributions to the topography of Earth's solid surface which

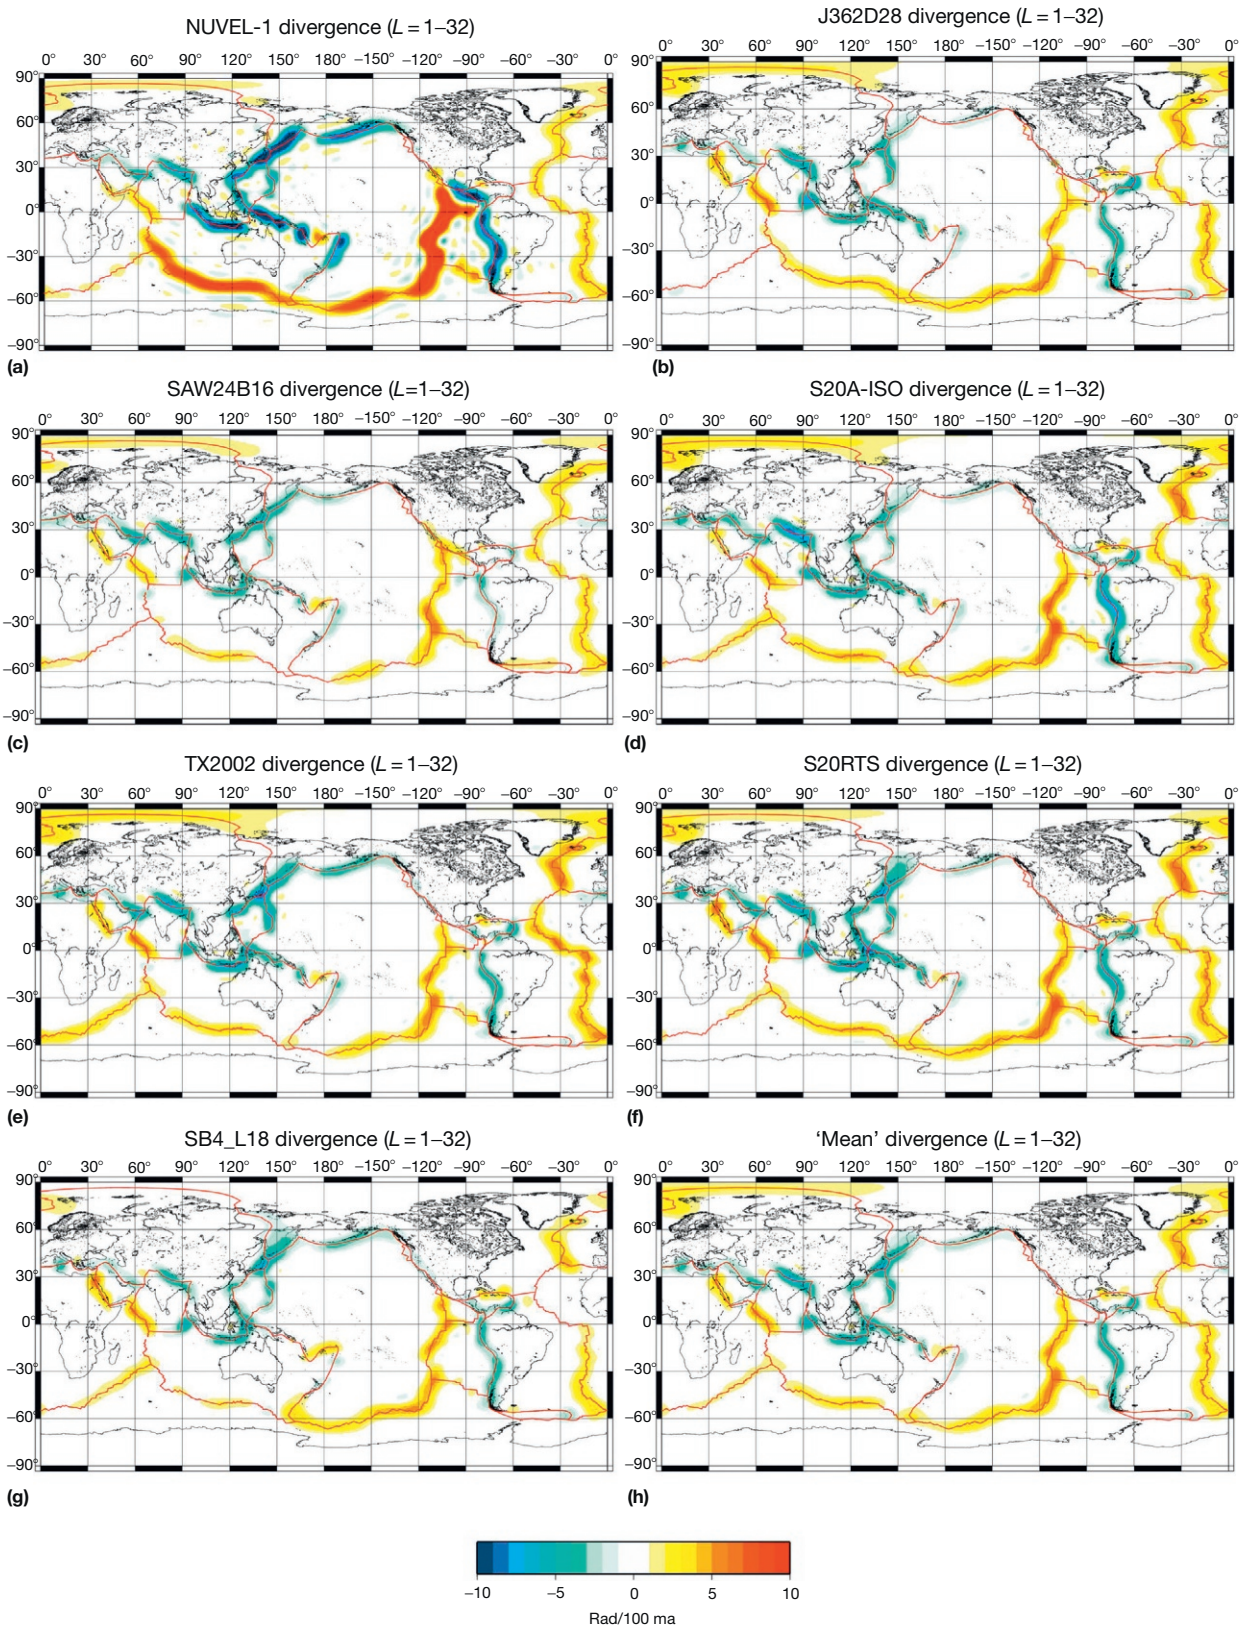

Figure 13 Tomography-based horizontal divergence of the tectonic plates. (a) Observed NUVEL-1 horizontal plate divergence (DeMets et al., 1990). (b)–(g) show the surface divergence predicted on the basis of tomography models *J362D28* (Antolik et al., 2003), *SAW24* (Mégnin and Romanowicz, 2000), *S20A-Iso* (Ekström and Dziewonski, 1998), *TX2002* (Grand, 2002), *S20RTS* (Ritsema et al., 1999), and *SB4_L18* (Masters et al., 2000), using the corresponding d ln ρ/d ln V_S scaling profiles in **Figure 12**. All shear-velocity heterogeneity models have been projected onto the common parameterization in expression [102] prior to calculating the predicted plate motions. (h) The 'mean' prediction of plate divergence obtained by calculating the statistical sample average of all the predictions (b)–(g). The observed and predicted plate motions shown here are all synthesized from spherical harmonics up to degree and order 32.

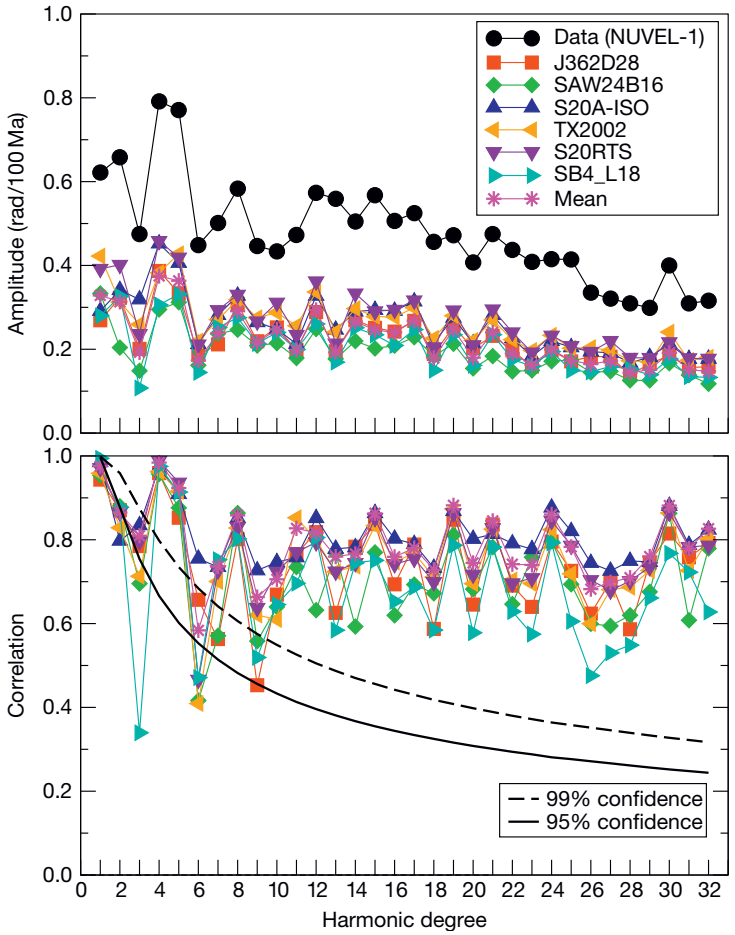

Figure 14 Spectral comparison of predicted and observed plate divergence. *Top frame* shows the degree variance, as defined in eqn [3], of the observed and predicted plate divergence fields shown in **Figure 13**. *Bottom frame* shows the degree correlations, as defined in eqn [4]. The black solid and dashed lines represent the 95% and 99% confidence levels, respectively.

Table 1 Comparison of observed[a] and predicted[b] horizontal plate divergence

Model	*NUVEL*[c]	J362D28	SAW24	S20A-Iso	TX2002	S20RTS	SB4_L18	*Mean*
rms	2.8	1.3	1.1	1.5	1.5	1.6	1.2	1.3
correl	–	0.77	0.74	0.83	0.78	0.80	0.74	0.82
var. red.	–	50%	44%	60%	56%	59%	45%	55%

Note: rms, root-mean-square amplitude, expressed here in units of 10^{-8} a^{-1}; correl, global cross correlation; var. red., variance reduction.
[a]Data and predictions (shown in **Figure 13**) are synthesized from spherical harmonics up to degree 32.
[b]Predictions employ the tomography model indicated at the top of each column and they use the corresponding velocity-to-density scalings in **Figure 12**.
[c]Horizontal divergence of the plates is derived from the NUVEL-1 (DeMets et al., 1990) description of present-day plate velocities.

arise from mantle convection. There has been some controversy as to origin and amplitude of Earth's dynamic topography, with some confusion as to how this dynamic topography should even be defined (e.g., Forte et al., 1993a,b; Gurnis, 1990; Gurnis, 1993). As will be discussed below, the interpretation of dynamic surface topography employed here, namely the topography arising from all density anomalies in the mantle (including those in the lithosphere), is not universally accepted. A detailed review and analysis of the opposing schools of thought in this debate has been presented by Pari (2001).

Numerous studies over the past three decades have focused exclusively on the topography of ocean floor, and the general conclusion is that this topography can be almost completely explained in terms of shallow, thermally induced density anomalies which arise from the age-dependent cooling of the oceanic lithosphere (e.g. Parsons and Sclater, 1977; Stein and Stein, 1992). The oceanic bathymetry is modeled in terms of isostatic compensation of density anomalies in the oceanic lithosphere and hence many studies have regarded this form of thermal isostasy as not being a 'dynamic' contribution to

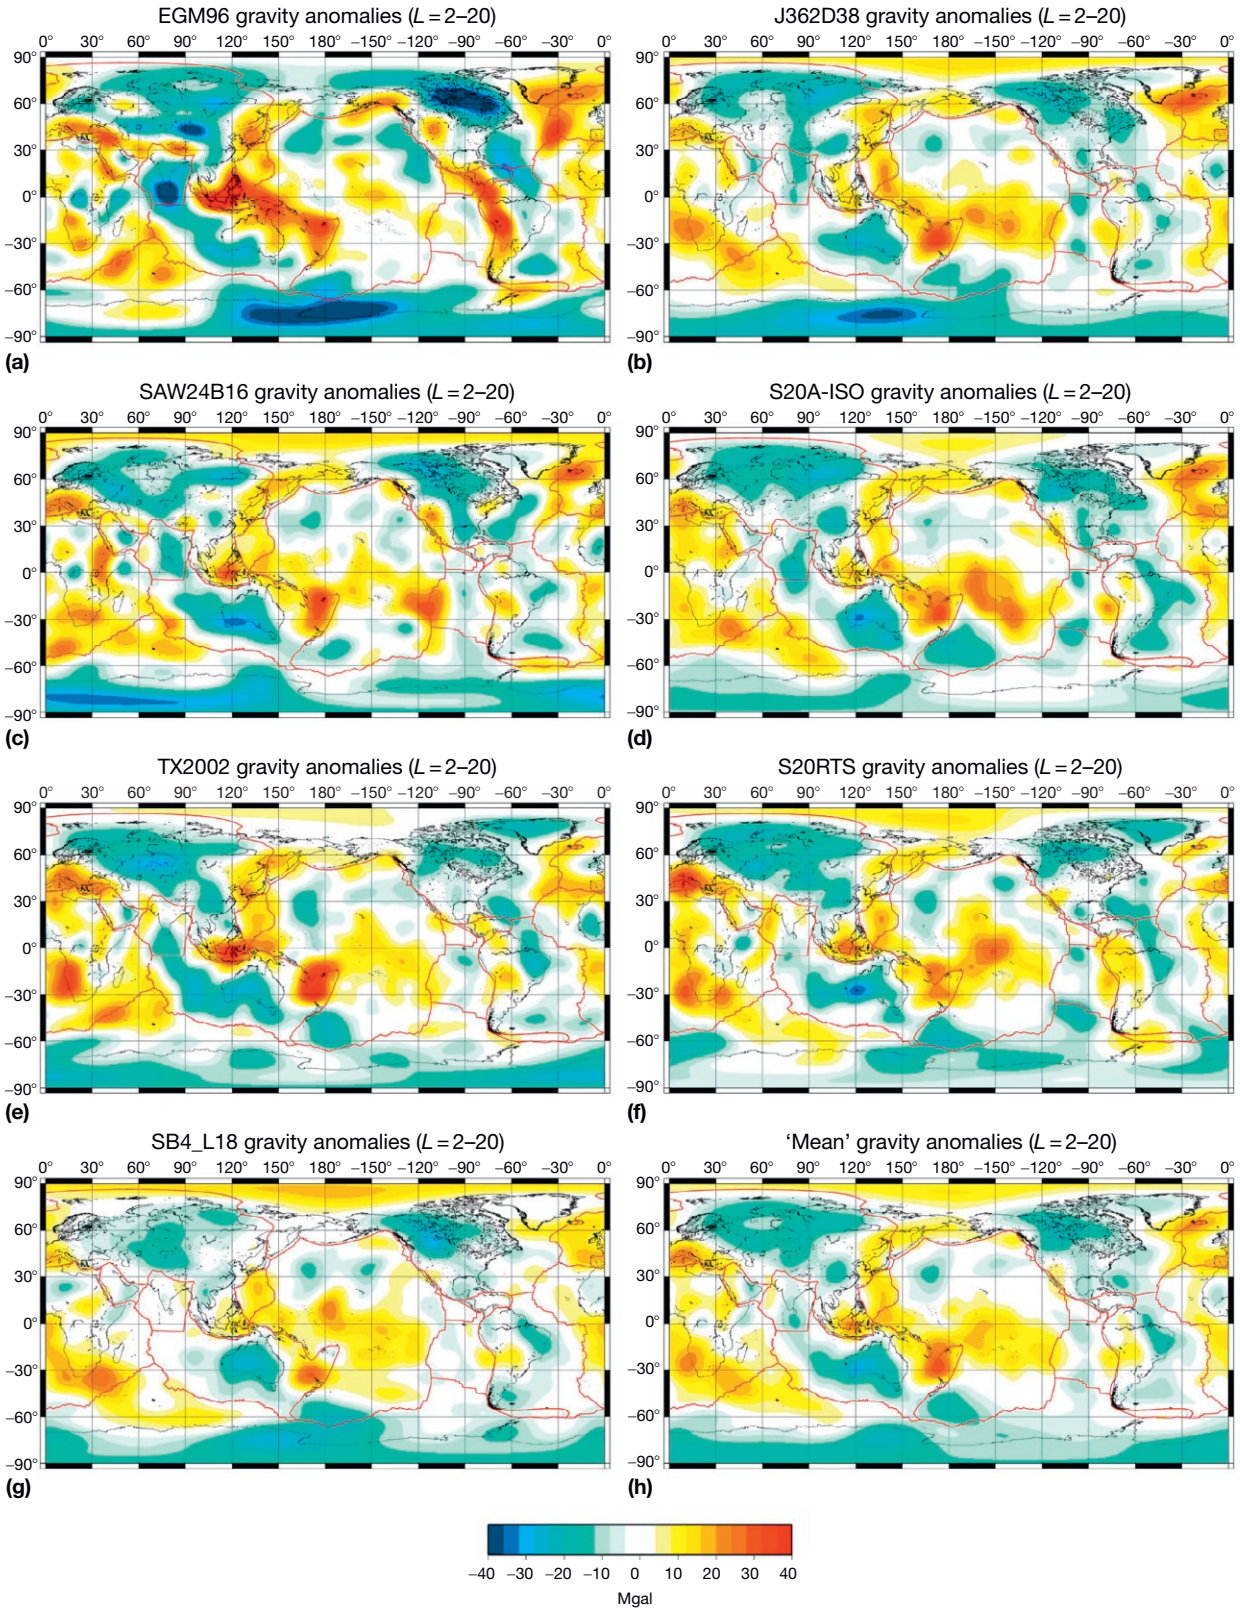

Figure 15 Tomography-based global free-air gravity anomalies. (a) Observed EGM96 anomalous free-air gravitational field (Lemoine et al., 1998). (b)–(g) show the free-air anomalies predicted on the basis of tomography models *J362D28* (Antolik et al., 2003), *SAW24* (Mégnin and Romanowicz, 2000), *S20A-Iso* (Ekström and Dziewonski, 1998), *TX2002* (Grand, 2002), *S20RTS* (Ritsema et al., 1999), and *SB4_L18* (Masters et al., 2000), using the corresponding d ln ρ/d ln V_S scaling profiles in **Figure 12**. surface topography. An adequate review of the extensive literature dealing with this interpretation of seafloor topography is well beyond the scope of this chapter, but previous studies of age-dependent oceanic bathymetry, with extensive references to past analyses, may be found in Doin and Fleitout (2000) and in Crosby et al. (2006). Possible causes for the deviation of oceanic bathymetry from that predicted by a simple cooling lithosphere model have been analyzed by Zhong et al. (2007) and they considered 'reheating' of old lithosphere due to deeper mantle flow. More recent analyses by Adam and Vidal (2010, 2011) have explored the validity, or not (Croon et al., 2011), of a revised interpretation of ocean-floor subsidence due to lithospheric cooling by again appealing to the influence of mantle flow in the asthenosphere.

Whether or not the thermal isostatic signal in seafloor bathymetry may be regarded as 'static' or 'dynamic' depends on the temporal variability of the structure of the upper thermal boundary layer (i.e., the lithosphere in oceanic regions) due to time-dependent mantle convection. A purely mechanical interpretation of the instantaneous, present-day isostatic compensation of thermal anomalies in the lithosphere ignores this back-ground time-dependence. The lateral temperature

variations in the cooling lithosphere are essentially maintained by a balance between vertical heat conduction and horizontal heat advection (e.g., Parsons and McKenzie, 1978; Jarvis and Peltier, 1982) and the latter is clearly a dynamic effect. In the absence of convection, the upper thermal boundary layer and the corresponding variations in oceanic bathymetry will vanish. The importance of time-dependent changes in the structure of the lithosphere, and hence the corresponding changes in the contribution to surface topography, is highlighted by the significant changes in plate tectonic velocities and plate geometries in the Cenozoic (e.g., Lithgow-Bertelloni and Richards, 1998) which suggest significant departures from steady-state conditions.

In the absence of convection, the only contribution to surface topography arises from the isostatic compensation of lateral variations in crustal thickness and crustal density. Earth's present-day topography is therefore the superposition of the crustal isostatic topography and the dynamic topography – as defined here – due to density anomalies in the mantle which are maintained by mantle convection (Forte et al., 1993b). The crustal isostatic topography is large and it explains most of the observed present-day topography on Earth (e.g., Forte and Perry, 2000; Pari and Peltier, 2000). The dynamic topography is obtained by subtracting the crustal isostatic topography from the observed topography and this therefore requires an accurate model of crustal structure. This requirement presents a major challenge because of the uneven and incomplete seismic sampling of global crustal thickness and also because of the significant uncertainties in constraining the density of the crust.

Until recently (2013), the most complete compilation of global crustal heterogeneity was model CRUST2.0 (Bassin et al., 2000). This global compilation has been updated to include new seismological constraints on crustal structure, yielding a new model of crustal heterogeneity: CRUST1.0 (Laske et al., 2013). A comparison of the dynamic topography fields inferred using CRUST2.0 and CRUST1.0 is presented in **Figure 17**. The most obvious difference is the greater amplitude of the long-wavelength variations in dynamic topography derived from CRUST1.0 relative to CRUST2.0, where the former are on average about 40% larger than the latter. This amplitude difference is most strongly expressed at the longest horizontal wavelengths (see **Figure 17c**), such that the dynamic topography of continents inferred with CRUST1.0 is substantially more depressed than with CRUST2.0, implying that the dynamic height of the mid-ocean ridges is also increased as a consequence.

The origin of these long-wavelength differences in non-isostatic or dynamic topography derived from two global crustal compilations is not yet clear at this time, but it does serve to aptly highlight the important impact of uncertainties in crustal structure in applying topographic constraints on density anomalies in the mantle, especially those in the upper mantle (**Figure 10e,f**). In the following analysis, we

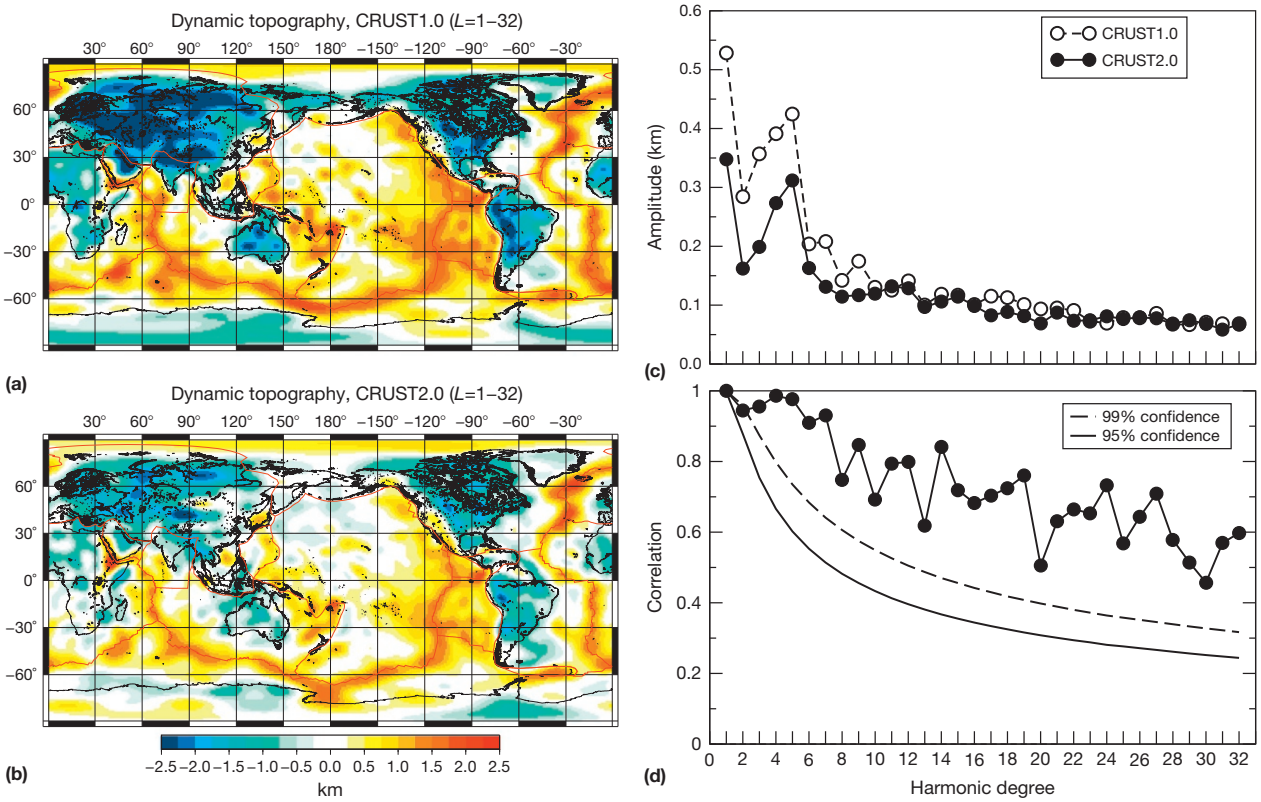

Figure 17 Long wavelength dynamic topography inferred from two crustal heterogeneity models. (a) Dynamic surface topography estimated by removing isostatically compensated crustal heterogeneity described by model CRUST1.0 (Laske et al., 2013) from the observed present-day surface topography. (b) Dynamic topography similarly inferred by removal of isostatically compensated CRUST2.0 (Bassin et al., 2000). (c) Comparison of spectral amplitudes (eqn [3]) from a spherical harmonic analysis of the inferred crustcorrected dynamic topography. (d) The degree correlations (eqn [4]) between the CRUST1.0and CRUST2.0 inferences of dynamic topography. The crust-corrected inferences of dynamic topography shown here are all synthesized from spherical harmonics up to degree and order 32.

employ the dynamic topography derived from the CRUST2.0 model (Figure 17b).

The observed and predicted dynamic topography fields, calculated on the basis of expressions (99) and using the kernels in Figure 10e,f, are presented in Figure 18. A quantitative spectral comparison of the predicted and observed dynamic topography is shown in Figure 19. In Table 3 is presented a detailed summary of the match between the predicted and observed topography fields. The topography kernels (Figure 10e,f) show that near-surface density anomalies provide the strongest contributions to the predicted surface topography (Figure 18) and that they will be in near-isostatic equilibrium, where perfect isostatic compensation corresponds to a kernel value of -1. We note that in the case of density anomalies which effectively see a no-slip surface boundary (given by expression 92), the condition of near-isostasy extends to depths of about 200 km (see Figure 10f).

In view of the debate (discussed above) concerning the magnitude of the thermal isostatic contributions to surface topography in oceanic regions, it is helpful to explore the relative importance of shallow (i.e. lithospheric) and deep-mantle (i.e. sub-lithospheric) buoyancy using the seismic tomography models. In this regard, it is useful to first evaluate the extent to which the tomography-based topography predictions incorporate the age-dependent cooling of the oceanic lithosphere. Tomography models employing seismic travel-time and/or surface wave data place strong constraints on lithospheric mantle heterogeneity and they contain a clear signature of the oceanic cooling history (e.g., Woodward and Masters, 1991; Su et al., 1992; Trampert and Woodhouse, 1996; Ritzwoller et al., 2004).

Here, we consider the global tomography models *SAW24* (Mégnin and Romanowicz, 2000) and *TX2002* (Grand, 2002), employed in Figure 18c and 18e, respectively. The age-dependent lateral temperature variations in the oceanic lithosphere were calculated using a simple halfspace cooling model with the same thermal parameters as the *GDH 1* plate-cooling model of Stein and Stein (1992). The seafloor age was determined using the Müller et al. (1997) digital isochrons. The global ocean basins were then sampled on a $1^\circ \times 1^\circ$ grid and for each grid cell the corresponding values of ocean age, shear velocity perturbation dV_S/V_S, and temperature perturbation ΔT were determined. These samples were then averaged into two million-year age bins and the resulting relationship between seismic shear velocity and temperature is plotted in Figure 20.

A linear regression analysis (solid lines in Figure 20) yields an excellent fit to the binned $V_S - T$ variation and the slopes of the regression lines provide estimates of the effective temperature derivative of S-velocity in the depth range 0–100 km. These estimated derivatives are $8.7 \times 10^{-5}\ \mathrm{K}^{-1}$ and $9.4 \times 10^{-5}\ \mathrm{K}^{-1}$ for models *SAW24* and *TX2002*, respectively. These effective thermal derivatives agree well with independent mineral physics values determined by Stixrude and Lithgow-Bertelloni (2005) which range between 8 and $9 \times 10^{-5}\ \mathrm{K}^{-1}$. These results confirm that the global tomography models considered in this study successfully resolve the pattern and amplitude of age-dependent cooling of the oceanic lithosphere.

The relative importance of surface topography due to lithospheric versus more deeply-seated density anomalies is illustrated in Figure 21. As expected, the topography contributions in oceanic regions from density anomalies in the upper 200 km of the mantle are dominated by the age-dependent cooling of the oceanic lithosphere. The accurate resolution of these shallow-mantle contributions to dynamic topography, which is dominated in the ocean basins by the cooling lithosphere signal, are important to obtaining good correlations (Table 3) to the crust-corrected inferences of global dynamic topography. Depressions in continental regions exceed observational estimates (Figure 18a) because the use of a purely depth dependent dln ρ/dln V_S scaling factor (Figure 12) does not resolve the intrinsic chemical buoyancy in the sub-continental mantle. This intrinsic buoyancy can be included in geodynamic models which allow for lateral variations of dln ρ/dln V_S in the shallow mantle (e.g., Forte and Perry, 2000; Deschamps et al., 2001).

The topography generated by sub-lithospheric buoyancy (Figure 21b), with rms amplitude equal to 410 m, is comparable to that generated by lithospheric density anomalies (Figure 21a) which has an rms amplitude equal 580 m. These sub-lithospheric contributions to topography in the central Pacific and Atlantic oceans, and in southern Africa, are surface expressions of deep-seated buoyancy with sources in the lower mantle (Figure 3). The depressions below the eastern and western margins of the Pacific (Figure 21b) may be interpreted in terms of present-day and Cenozoic subduction history (e.g. Lithgow-Bertelloni and Gurnis, 1997).

We note from Figure 18 that the amplitude of the predicted dynamic topography is somewhat larger than the crust-corrected estimate of the observed dynamic topography. Table 3 shows that the rms amplitude of the mean topography prediction is 25% larger than the observed topography. This discrepancy is in marked contrast to that of the predicted gravity and plate divergence fields (Tables 1 and 2) which are, on average, 40–50% smaller than the corresponding observed fields. The mismatched amplitudes of the predicted surface topography have motivated previous efforts (e.g., Le Stunff and Ricard, 1995, 1997) to introduce additional buoyancy forces in the mantle arising, for example, from undulations of the 670 km seismic discontinuity (e.g., Thoraval et al., 1995; Forte and Woodward, 1997b) which internally compensate the excess surface topography.

In assessing the significance of this discrepancy, in terms of mantle dynamics, it is important to recognize that the crustal correction employed in Figure 18a contains significant uncertainties which may in part be responsible for the mismatched amplitudes. Perhaps more important is the question of the validity of a purely depth-dependent velocity–density scaling (Figure 12) employed in the topography predictions. Such depth-dependence, which may be justified if one assumes that thermal effects on mantle heterogeneity dominate (e.g., Karato and Karki, 2001), is not a good approximation in the presence of large lateral variations in chemical composition. Such compositional heterogeneity is expected to be important in the shallow subcontinental mantle and it will oppose the local thermal buoyancy, implying significant reductions in the amplitude of continental surface topography (e.g., Forte and Perry, 2000).

To understand why the gravity (and plate motion) predictions, in contrast to the surface topography, have substantially smaller amplitudes than the observed fields, we must first appreciate that the global seismic data have difficulty resolving heterogeneity in the deep mantle, particularly in the southern

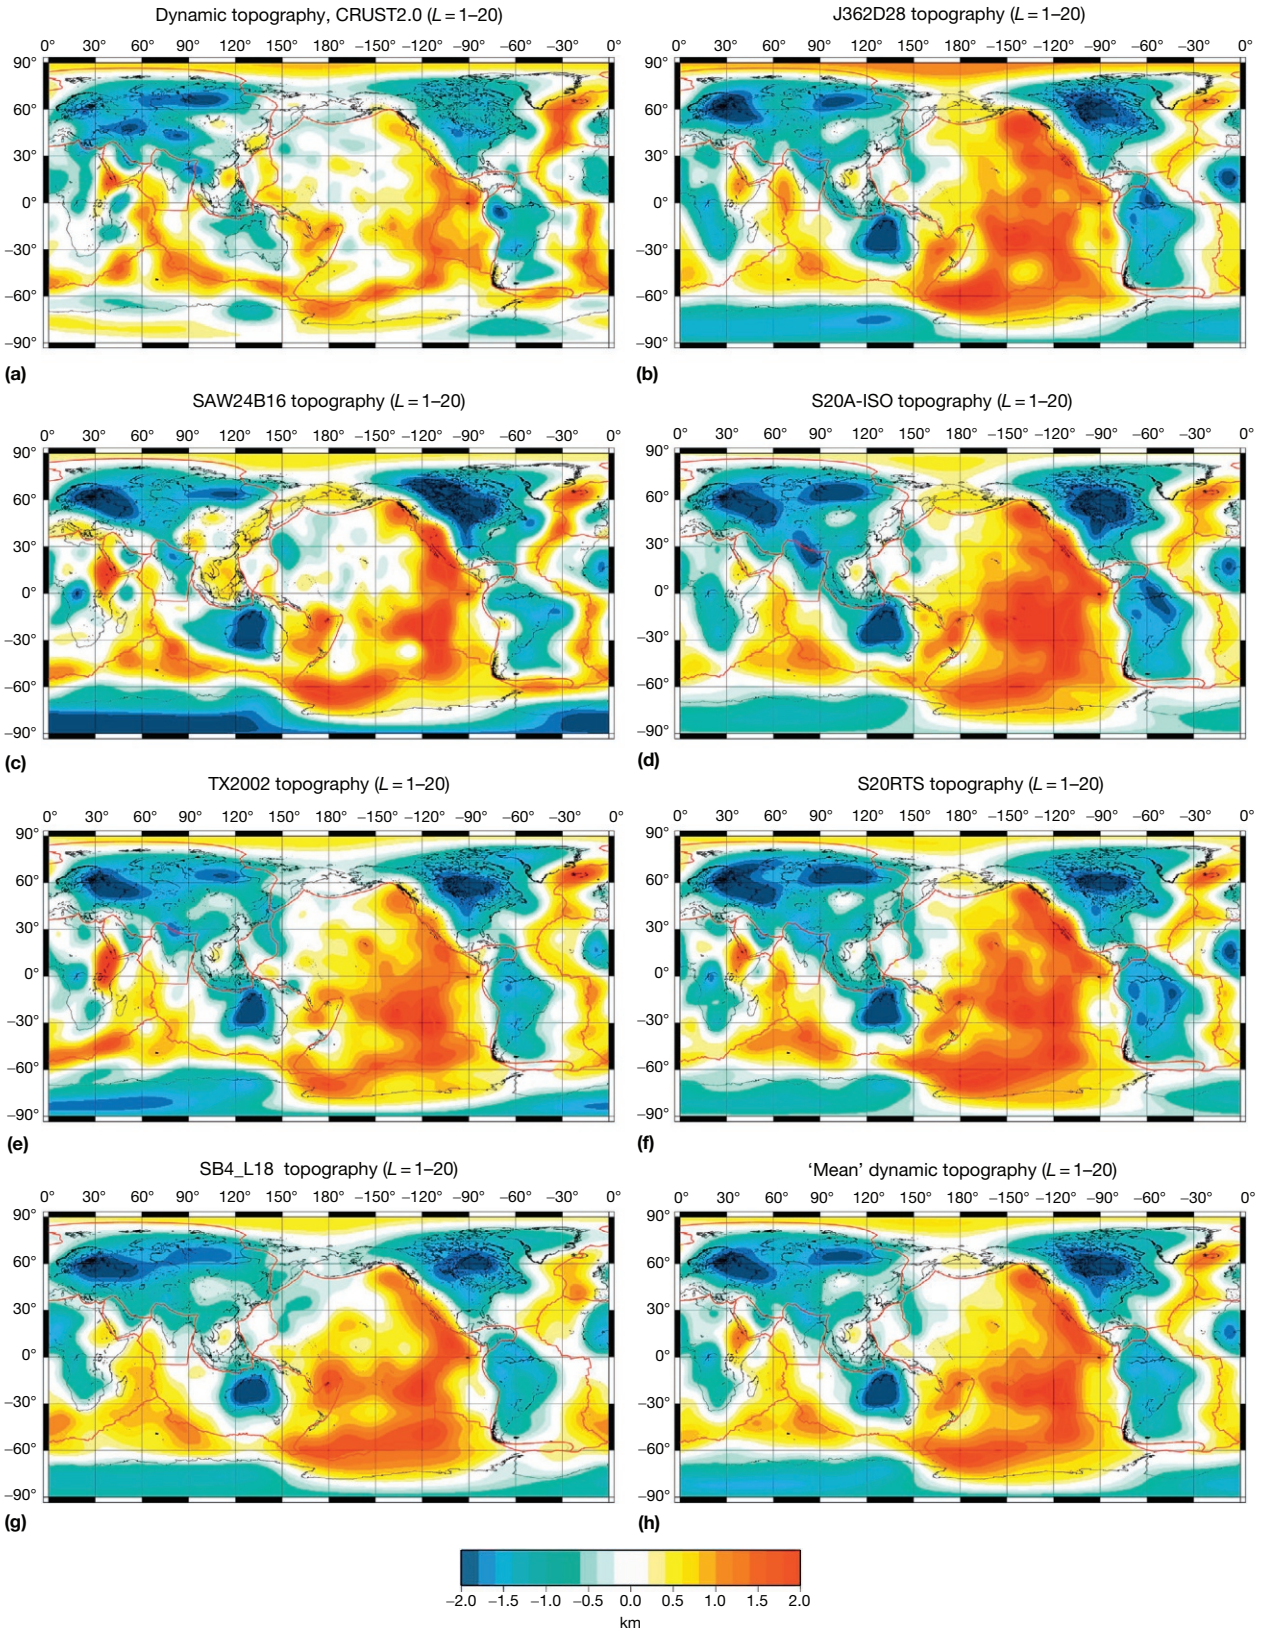

Figure 18 Tomography-based global dynamic surface topography. (a) Dynamic surface topography estimated by removing isostatically compensated crustal heterogeneity – described by model CRUST2.0 (Bassin et al., 2000) – from the observed present-day surface topography. (b)–(g) show the dynamic surface topography predicted on the basis of tomography models *J362D28* (Antolik et al., 2003), *SAW24* (Mégnin and Romanowicz, 2000), *S20A-Iso* (Ekström and Dziewonski, 1998), *TX2002* (Grand, 2002), *S20RTS* (Ritsema et al., 1999), and *SB4_L18* (Masters et al., 2000), using the corresponding d ln ρ/d ln V_S scaling profiles in **Figure 12**. All shear-velocity heterogeneity models have been projected onto the common parameterization in expression [102] prior to calculating the dynamic topography. (h) The 'mean' dynamic surface topography field obtained by calculating the statistical sample average of all the predictions (b)–(g). The crust-corrected and predicted dynamic topography shown here are all synthesized from spherical harmonics up to degree and order 20.

The black solid and dashed lines represent the 95% and 99% confidence levels, respectively.

Table 3 Comparison of observed[a] and predicted[b] dynamic surface topography

Model	*CRUST*[c]	J362D28	SAW24	S20A-Iso	TX2002	S20RTS	SB4_L18	*Mean*
rms	696	908	893	1002	860	972	849	873
correl	–	0.75	0.76	0.80	0.78	0.78	0.79	0.87
var. red.	–	25%	30%	22%	41%	24%	44%	47%

Note: rms, root-mean-square amplitude, expressed here in units of *m*; correl, global cross correlation; var. red., variance reduction.
[a]Data and predictions (shown in **Figure 18**) are synthesized from spherical harmonics up to degree 20.
[b]Predictions employ the tomography model indicated at the top of each column and they use the corresponding velocity-to-density scalings in **Figure 12**.
[c]The global dynamic surface topography obtained by subtracting CRUST2.0 (Bassin et al., 2000) isostatic crust from the observed topography.

hemisphere (e.g., Forte et al., 1994; Simmons et al., 2006). This difficulty does not apply to the shallow mantle where, as shown above (**Figure 20**), the tomography models are able to successfully resolve the cooling oceanic lithosphere. The predicted surface topography is dominated by the density anomalies located in the upper mantle, whereas the gravity predictions contain significant contributions from lower-mantle density anomalies (**Figure 10**). Joint inversions of global seismic and convection-related data sets have shown that increased amplitudes of the predicted gravity anomalies and substantially improved fits to the global gravity data can be achieved by modifying deep-mantle heterogeneity in a way that is consistent with both the seismic and geodynamic constraints (e.g., Forte et al., 1994; Simmons et al., 2006, 2007, 2009, 2010). Such modifications to lower-mantle heterogeneity have little impact on the amplitude of the predicted surface topography. These basic observations suggest that current mismatches between the amplitudes of the predicted and observed dynamic topography are not more significant, or fundamentally different, from the mismatch between the other predictions (i.e., gravity and plate motions) and their corresponding observables.

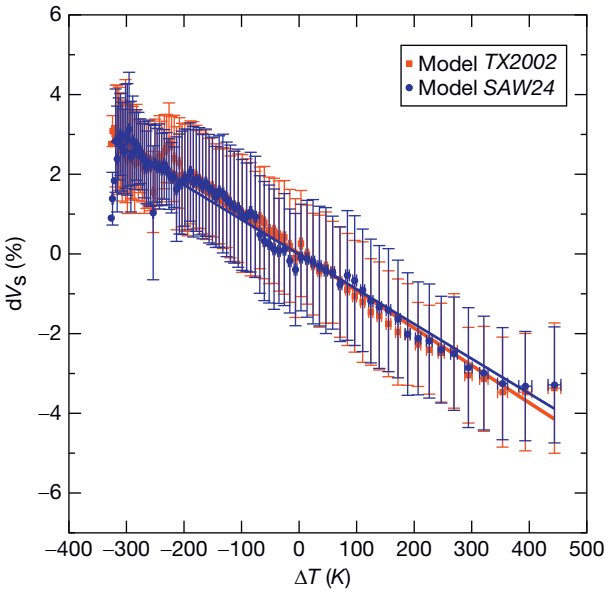

Figure 20 Comparison of seismic shear-velocity and temperature anomalies in the oceanic lithosphere. Seismic shear-velocity anomalies, vertically averaged in the depth interval 0–100 km, are derived from tomography models *SAW24* (Mégnin and Romanowicz, 2000) and *TX2002* (Grand, 2002). The S-velocity anomalies, measured relative to the global oceanic mean value, were averaged into 2 Ma age bins using the global ocean-age compilation of Müller et al. (1997). The age-dependent temperature variations in the oceanic lithosphere were determined using a simple half-space cooling model with the same thermal parameters as the *GDH*1 plate model of Stein and Stein (1992). These temperature variations were vertically averaged down to 100 km depth and subsequently averaged into 2 Ma age bins. The temperature anomalies are measured relative to the global oceanic mean value. The vertical and horizontal error bars represent one standard deviation relative to the average shear velocity and temperature, respectively, in each age bin. The solid blue and red lines are the best-fitting linear regression lines for models *SAW24* and *TX2002*, respectively.

1.27.3.6 Predicted CMB Topography

Tomography-based studies of the flow-induced deformations of the CMB have been rather limited (e.g., Forte et al., 1993a, 1995a,b; Hager et al., 1985) relative to the much greater number of studies that have focused on the surface geoid or topography. This is in large part a consequence of the uncertain and often contrasting inferences of the CMB topography, which have been derived from inversions of seismic phases, which are sensitive to this topography (e.g., Boschi and Dziewonski, 2000; Garcia and Souriau, 2000; Morelli and Dziewonski, 1987; Obayashi and Fukao, 1997; Rodgers and Wahr, 1993; Sze and van der Hilst, 2003). A detailed discussion of the seismological uncertainties and difficulties in obtaining reliable global images of the CMB topography may be found in Garcia and Souriau (2000).

The most accurate constraint on the topographic undulations of the CMB is derived from space-geodetic analyses of Earth's nutations. A brief review of these constraints was presented in **Section 1.27.2.1**. Unfortunately, these geodetic analyses can only constrain the excess flattening or dynamic ellipticity of the CMB – albeit with high precision – and this corresponds to only one coefficient ($\ell=2, m=0$) in a full spherical harmonic expansion (expression [1]) of the spatially varying CMB topography field. This constraint on excess CMB flattening is included in all the Occam-inferred $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ scaling profiles in **Figure 12**.

For the purpose of comparison, we consider a relatively recent seismological inference of the CMB topography (**Figure 22(a)**) obtained by Boschi and Dziewonski (2000) (henceforth referred to as 'BD2000') on the basis of seismic PcP and PKP travel-time delays. The flow-induced CMB topography predicted on the basis of the Occam-inferred $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ profiles (**Figure 12**) and, using the kernels in **Figure 10(g)** and **10(h)**, is presented in **Figure 22**. All predictions of CMB topography shown here exactly reproduce the geodetically constrained 400 m excess CMB ellipticity. A quantitative spectral analysis (**Figure 23**) of the predicted CMB topography fields shows that they are strongly dominated by the horizontal wavelengths corresponding to harmonic degrees $\ell=2,3$. In **Table 4** is presented a detailed summary of the match between the predicted and observed CMB topography fields.

The overall spatial correlation between the predicted maps of flow-induced CMB topography and the BD2002 model (**Figure 22**) is quite good; however, it is quite clear that there is a significant difference in the overall amplitude. The CMB topography obtained on the basis of the tomography-based flow calculations is approximately a factor of three to four times smaller than that in BD2002. Although, as noted earlier (**Section 1.27.3.3**), there likely exists an inherent damping in the flow predictions, it is not possible to increase the amplitude of the predicted CMB topography (by increasing, e.g., the magnitude of the $\mathrm{d}\ln\rho/\mathrm{d}\ln V_S$ scaling) without at the same time significantly degrading the fit to the other geodynamic observables. The ±1.5 km-scale undulations in the predicted, flow-induced CMB topography are in the range estimated by Garcia and Souriau (2000) for horizontal wavelengths in excess of 1200 km.

1.27.4 Joint Seismic–Geodynamic Inversions for 3-D Structure and Flow in the Mantle

In the preceding sections, all interpretations of the 3-D structure and flow in the mantle, and the predicted surface geodynamic observables associated with this flow, have been entirely based on purely seismic inversions for 3-D lateral heterogeneity in the mantle. This approach, in which previously published seismic tomography models are converted a posteriori into an equivalent mapping of 3-D density anomalies, as described in **Section 1.27.3.2**, is followed in essentially all analyses of tomography-based mantle convection that have been published since the advent of the first global tomography models in the mid-1980s (e.g., Forte and Peltier, 1987) up to the present (e.g., Alisic et al., 2012; Becker and Faccenna, 2011; Conrad et al., 2011).

In the following, we will instead consider how the seismic constraints on global heterogeneity in the mantle may be simultaneously inverted with independent constraints on 3-D structure from geodynamic and mineral physical data to obtain a new generation of mantle tomography models that successfully reconcile all these constraints, thereby providing new insights in the structure and dynamics of the mantle convective flow.

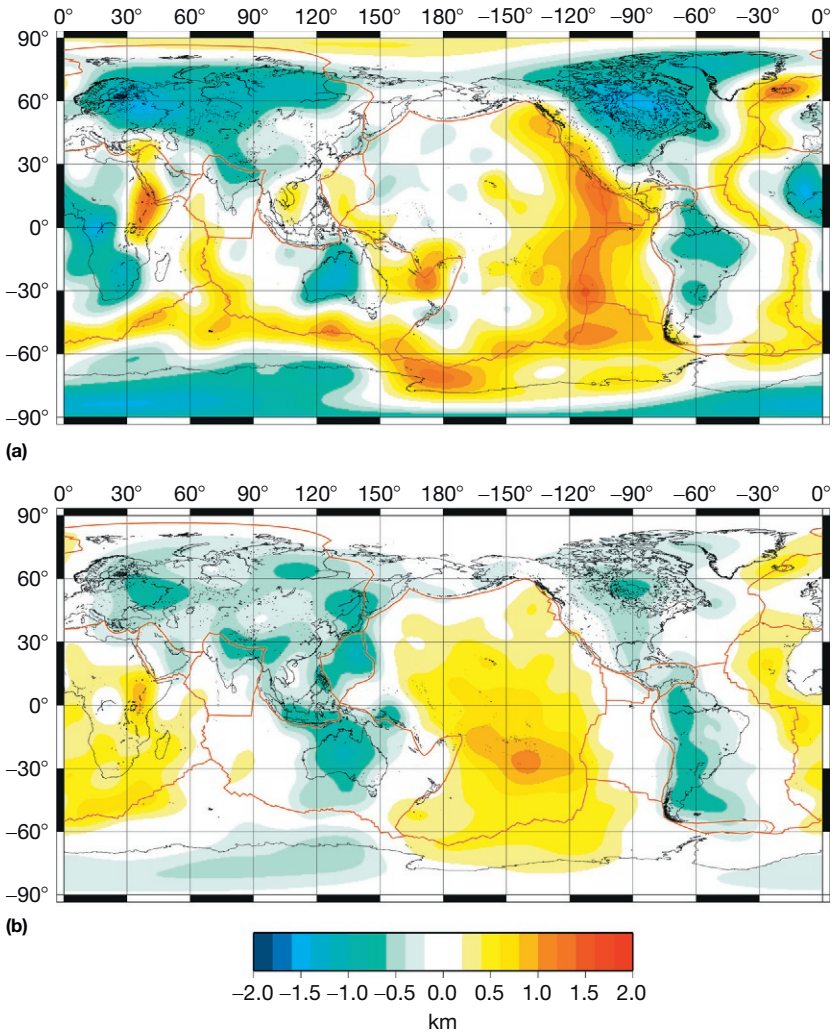

Figure 21 Shallow versus deep-mantle contributions to surface topography. (a) Surface topography predicted on the basis of tomography-derived density anomalies in the upper 200 km of the mantle. (b) Surface topography predicted on the basis of all density anomalies below 200 km depth. In both cases, the density anomalies are derived from tomography model *TX2002* (Grand, 2002) and using the corresponding d ln ρ/d ln V_S scaling profiles in **Figure 12**. The summation of the topography fields in maps (a) and (b) yields the total field shown in **Figure 18(e)**. All fields are synthesized from spherical harmonics up to degree and order 20.

1.27.4.1 Deficiencies in Mantle Flow Models Based on Pure Seismic Tomography Inversions

While the a posteriori scaling of mantle tomography models, derived purely from seismic data, into equivalent density heterogeneity models has provided reasonably good fits to the global convection-related data sets, there remain significant unexplained misfits to these surface geodynamic constraints. More specifically, the variance reductions achieved in fitting long-wavelength global plate motions, gravity, and dynamic topography anomalies are 55%, 41%, and 47%, respectively. These misfits characterize the summary or '*mean*' predictions in the final column of **Tables 1–3**. These results, obtained with optimized depth-dependent velocity-to-density scaling factors, suggest that, on average, about 50% of the power in convection-related data cannot be explained by the a posteriori scaling of the currently available seismic tomography models.

In assessing the origin of the outstanding misfit between the tomography-based predictions of the convection-related observables and the corresponding data, a number of possible deficiencies in the mantle flow calculations should be considered. As discussed in **Section 1.27.2.3.1**, a major simplification in the mantle flow modeling is the assumption that the sublithospheric viscosity of the mantle varies with depth only. We should note, however, that these flow models incorporate the effect of what is arguably the greatest-amplitude lateral heterogeneity of rheology in the solid Earth: the tectonic plates. All flow predictions presented in the preceding sections are carried out with surface tectonic plates coupled to the mantle flow and driven by this flow. The outstanding question is therefore whether LVV in the underlying mantle can account for a significant fraction of the current misfit to the geodynamic data.

In addressing the impact of LVV on global convection-related surface data, Moucha et al. (2007) found that global-

The amplitudes correspond to the top values (±4.5 km) in the bottom scale bar. (b)–(g) show the CMB topography predicted on the basis of tomography models *J362D28* (Antolik et al., 2003), *SAW24* (Mégnin and Romanowicz, 2000), *S20A-Iso* (Ekström and Dziewonski, 1998), *TX2002* (Grand, 2002), *S20RTS* (Ritsema et al., 1999), and *SB4_L18* (Masters et al., 2000), using the corresponding d ln ρ/d ln V_S scaling profiles in **Figure 12**. All shear-velocity heterogeneity models have been projected onto the common parameterization in expression [102] prior to calculating the CMB topography. (h) The 'mean' CMB topography field obtained by calculating the statistical sample average of all the predictions (b)–(g). The amplitudes for (b)–(h) correspond to the bottom values (±1.5 km) in the bottom scale bar. The observed and predicted CMB topography shown here are all synthesized from spherical harmonics up to degree and order 20.

scale heterogeneity in viscosity, in which the amplitude of the LVV is equivalent to the variations in the mean depth-dependent viscosity (up to three orders of magnitude), yields predictions that differ by about 20% from those obtained by neglecting LVV. These differences were also found to be substantially smaller than the differences obtained using two different global tomography models. These results suggest that LVV in the mantle are not likely to be the principal source of the outstanding 50% misfit between the current tomography-based flow predictions and the surface geodynamic observables.

Another, possibly major, source of misfit may be due to the neglect of lateral variations in the scaling between seismic velocity and density, as would be the case in the presence of significant compositional heterogeneity in the mantle. The predicted geodynamic observables presented in Section 1.27.3 are obtained using a purely depth-dependent scaling, as expected if thermal contributions to mantle heterogeneity are assumed dominant (see, e.g., Figure 12).

A detailed exploration of the amplitude and distribution of chemical heterogeneity inferred on the basis of previously published tomography models, to achieve maximum agreement with the surface geodynamic data, was carried out by Forte (2007). This analysis allowed for explicit lateral variations in the velocity-to-density scaling by inverting for different scaling factors in regions of the mantle characterized by anomalously hot material (e.g., rising plumes) and anomalously cold material (e.g., subducting lithosphere in the lower mantle and deep subcontinental roots in the upper mantle). This parameterization of chemical heterogeneity is analogous to that advocated by Xu et al. (2008), in which the composition of the mantle is assumed to be a mechanical mixture of basalt and harzburgite generated by a long-term history of partial melting at mid-ocean ridges and subsequent transport into the deep mantle by subducting lithosphere. The inversions by Forte (2007) for a laterally variable scaling, associated with 'hot' and 'cold' regions of the mantle, yielded an improved fit to the surface convection-related data sets, but the improvement of about 10% is largely insufficient to account for the outstanding 50% misfit to these data.

We refer the interested reader to Forte (2007) for a detailed discussion of the geodynamic and mineral physical interpretation of global tomography models, derived solely from seismic data, in terms of compositional heterogeneity in the mantle. An alternative view of compositional heterogeneity in the mantle, based on 'probabilistic' (purely seismic) inversions for 3-D mantle structure, is presented in Mosca et al. (2012).

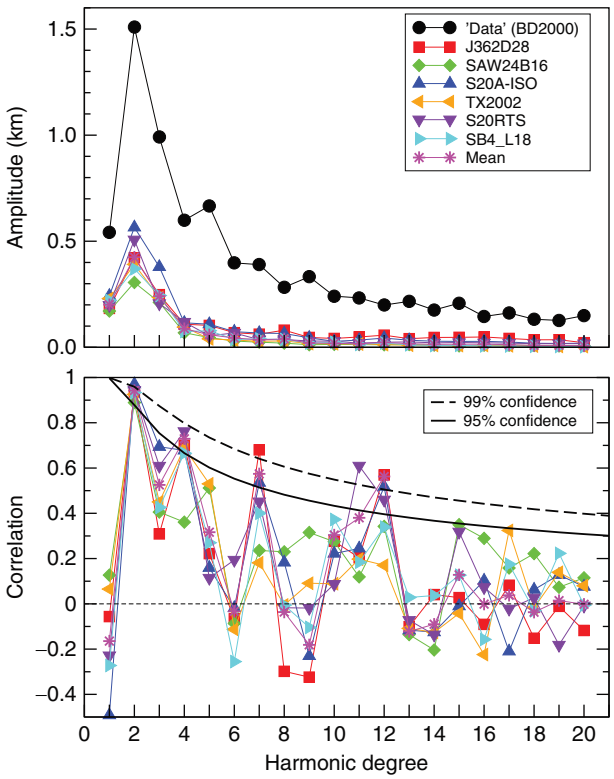

Figure 23 Spectral comparison of predicted and observed CMB topography. *Top frame* shows the degree variance, as defined in eqn [3], of the observed and predicted CMB topography fields shown in Figure 22. *Bottom frame* shows the degree correlations, as defined in eqn [4]. The black solid and dashed lines represent the 95% and 99% confidence levels, respectively.

1.27.4.2 Mantle Flow Modeling Based on Tomography Models Derived from Seismic Data Alone Is Insufficient

The considerations presented in the previous section suggest that the origin of the outstanding (nearly 50%) misfit between the tomography-based predictions of the convection-related observables and corresponding data is not likely to be resolved by the introduction of additional complexity in the mantle flow theory, such as LVV or lateral heterogeneity in major element mantle composition.

The main reason for the substantial misfit of the tomography-based geodynamic predictions is most likely due to a basic limitation inherent in published tomography models derived solely from global seismic data. This limitation arises

Table 4 Comparison of seismically observed[a] and predicted[b] CMB topography

[b]Predictions employ the tomography model indicated at the top of each column and they use the corresponding velocity-to-density scalings in Figure 12.
[c]CMB topography derived by Boschi and Dziewonski (2000) from global tomographic inversion of seismic delay times.

because the data sets employed in the derivation of these tomography models do not provide unique constraints on lateral heterogeneity throughout the mantle. It has long been understood that the amplitude of seismically inferred heterogeneity is poorly constrained over a large depth interval in the mid and lower mantle and that direct comparisons between different models published in the literature yield ambiguous information (e.g., deWit et al., 2012; Masters et al., 2000). This ambiguity or nonuniqueness is the direct consequence of the existence of a large null-space in the seismic data constraints on lateral heterogeneity in the mantle (e.g., deWit et al., 2012).

The relatively weak global seismic constraints in the mid-mantle region were explicitly shown in Forte et al. (1994) where it was also demonstrated that the seismic sampling of heterogeneity in the Southern Hemisphere portion of the deep mantle was weak. This limited sampling of mantle heterogeneity in the Southern Hemisphere is especially marked in tomography models derived predominantly from direct arriving seismic waves (e.g., Li et al., 2008). A clear illustration of the outstanding difficulty in resolving mantle heterogeneity in the depth interval 600–2000 km is provided by the comparison of recently published tomography models presented by Ritsema et al. (2011, see Figures 1 and 11 in their paper).

The mid-mantle region is of great importance in geodynamic modeling because the mantle flow excited by buoyancy forces in this region explains a significant fraction of the convection-related surface data such as the long-wavelength free-air gravity anomalies (see **Figure 10(c)** and **10(d)**) and the tectonic plate motions (see **Figure 10(b)**). An accurate resolution of mid-mantle buoyancy forces, over a large depth interval (from about 400 to 2000 km depth), is also crucial for understanding the amplitude and spatial pattern of flow across the entire mantle, with direct implications for the extent to which the flow is vertically stratified (e.g., Forte, 2000; Forte and Woodward, 1997a,b; Simmons et al., 2006).

Currently published seismic tomography models do not represent the full range of models that are compatible with the global seismic data sets (e.g., deWit et al., 2012). Although the tomographic inversions may contain far more data than the parameters used to represent the 3-D models (e.g., Boschi and Dziewonski, 2000; Kustowski et al., 2008; Li et al., 2008; Ritsema et al., 2011), the data nonetheless provide limited and nonuniform sampling of deep-mantle heterogeneity. This limitation arises in large part from the geographically restricted distribution of seismic stations and earthquake sources. Smoothness and amplitude-damping constraints are therefore used to regularize the tomographic inversions in order to stabilize the heterogeneity in those portions of the mantle that are poorly sampled by the seismic data. If these regularization conditions are changed, then so are the tomography models that result from the inversions. Furthermore, the result of any seismic inversion will be dependent on a number of other factors that include model parameterization, data weighting, and seismic wave theory employed in the data interpretation. Changes in any one of these ingredients will result in different 3-D seismic models that will yield different and, in some cases, conflicting geodynamic interpretations of mantle heterogeneity.

Since any individual seismic tomography model is only a single realization out of the infinitely large space of models that are compatible with the global seismic data, it is not sufficient to test mantle flow hypotheses, or to evaluate the significance of predicted geodynamic surface observables, on the basis of the published tomography models. As initially shown by Forte et al. (1994) and subsequently by Simmons et al. (2006, 2007, 2009, 2010), a robust test of different mantle flow scenarios, and the degree to which mantle heterogeneity is controlled by lateral temperature variations, is to check the plausibility of these scenarios directly against the widest range of available seismic and geodynamic data. This testing can be effectively accomplished by simultaneously inverting all data constraints in a single large-scale inversion. These joint inversions will immediately reveal the extent to which these different constraints on mantle structure, composition, and flow can be simultaneously and successfully reconciled by at least one model of 3-D mantle heterogeneity.

1.27.4.3 Simultaneous Inversions of Seismic, Geodynamic, and Mineral Physical Data

In essence, a joint tomographic inversion of multiple and distinct classes of geophysical data involves the search for (a) 3-D mantle heterogeneity model(s) that can simultaneously satisfy all these data. This was the approach developed by Forte et al. (1994) and Forte and Woodward (1997a,b), who implemented a method for jointly inverting global seismic and geodynamic data. The key feature of these joint inversions, which sets them apart from classical tomography inversions of seismic data alone, is the inclusion of constraints directly relating to buoyancy-induced mantle flow, in particular the relationship between this flow and convection-related surface data. These joint inversions are thus able to directly test to what extent the seismic constraints on mantle heterogeneity are compatible with entirely independent geodynamic constraints on the same structure (e.g., Simmons et al., 2006). This joint inversion procedure also allows a direct test of the degree to which mantle heterogeneity is controlled by the thermal anomalies maintained by the mantle convection process (e.g., Forte and Woodward, 1997a,b; Simmons et al., 2009).

1.27.4.3.1 Geodynamic and seismic data sets

The principal geodynamic surface observables that can be used to effectively constrain the 3-D structure and dynamics of the convecting mantle were described previously in **Section 1.27.2.1**, and they include the global free-air gravity anomalies, the crust-corrected dynamic topography, the present-day tectonic plate velocities, and the excess 'flattening' or ellipticity of the CMB (all fields are shown in **Figure 2**).

The theoretical, linear-integral relationship between the spherical harmonic coefficients of any one of these observable geodynamic fields and the corresponding harmonic coefficients of the internal density perturbations in the mantle is provided by geodynamic kernel or 'response' functions, as shown in eqn [104]. In the recent series of joint seismic–geodynamic tomography inversions carried out by Simmons et al. (2007, 2009, 2010), the geodynamic response functions have been calculated on the basis of the radial viscosity profile, shown in **Figure 9**, derived from the simultaneous inversions of GIA and convection data by Mitrovica and Forte (2004). The depth-dependent geodynamic kernel functions that are derived on the basis of

this geodynamically inferred viscosity profile are presented in Figure 10. These kernels will be employed in the joint tomography inversions described in the succeeding text.

The seismic data employed in the joint seismic–geodynamic tomography inversions consist of over 46 000 travel times of shear body waves (S waves) that were measured by Simmons (2007) and Grand (2002) through cross correlation of synthetic waveforms (for 1-D reference Earth model) and observed waveforms. These travel-time measurements were made mainly on teleseismic, horizontally polarized (SH) shear waves, including reflected multiple phases: Sn and ScSn, where n is the number of surface reflections and c denotes a reflection from the CMB. The data set also contains vertically polarized (SV) teleseismic shear phases: SKS and SKKS. An additional, critically important component of the global data set consists of regional, shallow-turning SH phases and surface-reflected multiples that are triplicated due to sharp velocity increases in the upper-mantle transition zone (Grand, 1994). These shallow phases provide increased lateral resolution of strongly varying upper-mantle structures that teleseismic body waves do not provide. A thorough discussion of the seismic data measurement and modeling procedure is provided by Simmons (2007), with a detailed summary to be found in Simmons et al. (2006).

1.27.4.3.2 Joint inversion procedure

The joint inversion of the seismic and geodynamic data sets described in the preceding section is carried out by first parameterizing the heterogeneity in the mantle in terms of individual blocks, in each of which the heterogeneity is assumed to be constant. This block representation of 3-D mantle structure is accomplished by dividing the mantle into 22 layers, from the surface down to the CMB, where the layer thickness varies between 75 (in the upper mantle) and 150 km (in the lower mantle). The lowermost mantle layer (layer 22), representing the heterogeneity in the seismic D″ region, has a thickness of 240 km. Each layer is then divided into rectangular voxels whose sides have a horizontal dimension of 275 km. This parameterization of mantle structure yields nearly 99 000 blocks.

The suite of convection-related geodynamic observables (Figure 2) are combined with the global seismic data into a single linear system, yielding an inverse problem that simultaneously constrains seismic velocity and density heterogeneity as follows:

$$\begin{pmatrix} \mathbf{L} \\ \lambda_G \mathbf{G}(R_{\rho/s}) \\ \lambda_{cmb} c(R_{\rho/s}) \\ \lambda_R \mathbf{R} \end{pmatrix} \mathbf{m} = \begin{pmatrix} \mathbf{r} \\ \lambda_G \mathbf{s} \\ \lambda_{cmb} e \\ \mathbf{0} \end{pmatrix} \qquad [109]$$

in which the heterogeneity in the mantle, denoted here by the column vector $\mathbf{m}$ with ~99 000 components, is expressed in terms of seismic slowness perturbations. The seismic constraints on mantle heterogeneity are incorporated via $\mathbf{L}$, a sparse matrix of ray path lengths (seismic sensitivities), and $\mathbf{r}$, the shear wave travel-time residuals. $\mathbf{L}$ has a row dimension of ~46 000, corresponding to the total number of seismic travel times. The geodynamic constraints are incorporated through $\mathbf{G}$, a fully populated matrix containing the viscous flow sensitivity kernels (Figure 10), where each row corresponds to a specific spherical harmonic component of the free-air gravity, plate divergence, and dynamic topography constraints. Since each of these fields is expressed by truncated spherical harmonic expansions up to a maximum harmonic degree $\ell = 16$, there are a total of 861 rows in $\mathbf{G}$. Each component of the column vector $\mathbf{s}$ contains the spherical harmonic coefficients of the geodynamic observables (Figure 2(a)–2(c)) normalized by their estimated standard error. The row vector c is the viscous flow response function (i.e., kernel) for the $\ell = 2$ zonal harmonic coefficient describing the excess ellipticity of the CMB (Figure 2(d)), contained in the data component e.

The inversion is stabilized through the introduction of a regularization or smoothing operator represented by the matrix $\mathbf{R}$, designed to yield a second-order smoothing in both the vertical (layers) and horizontal (blocks) directions (Simmons, 2007). The λ terms in eqn [109] are scalar quantities that determine the relative weights applied to the seismic, geodynamic, and smoothing constraints.

Since the geodynamic data are strictly related to density perturbations rather than the seismic heterogeneity (see Section 1.27.3.2), we must also incorporate a relationship between perturbations of density (ρ) and shear wave velocity (V_S). In eqn [109], the density-to-velocity relationship is identified by $R_{\rho/s}$, which is defined by

$$R_{\rho/s} = \frac{d \ln \rho}{d \ln V_S} \qquad [110]$$

The selection of appropriate density-to-velocity scaling is clearly important in ensuring that the independent constraints on mantle heterogeneity provided by the seismic and geodynamic data can be fully reconciled. This reconciliation also bears on the extent to which this heterogeneity is dominated, or not, by the thermal structure maintained by the convecting mantle. These considerations are discussed in the next section.

Finally, the joint linear system in [109] is inverted using an iterative LSQR inversion technique (Paige and Saunders, 1982). Special attention is required to ensure successful convergence of the iterations, owing to the mixed (i.e., sparse and fully populated) character of the joint matrix on the left-hand side of expression [109]. A modified LSQR scheme was therefore implemented by Simmons (2007). This modified scheme also permits an independent specification of the density-to-velocity scaling in eqn [110] such that it is fully decoupled from the geodynamic kernels in expression [105]. In a further modification introduced by Simmons et al. (2010), the LSQR iterations are embedded in a very fast simulated annealing process that ensures maximum consistency between the seismic and geodynamic constraints on 3-D mantle structure.

1.27.4.4 Relating Mantle Density and Seismic Velocity Anomalies

The principal hypothesis employed in previous joint inversions of global seismic and geodynamic data sets (Forte and Woodward, 1997b; Forte et al., 1994; Simmons et al., 2007, 2009, 2010) is that the lateral temperature variations maintained by the process of thermal convection are the dominant source of lateral heterogeneity in the mantle. The most notable and generally accepted exception to this thermal dominance is the

heterogeneity associated with the so-called tectosphere (e.g., Jordan, 1981), namely, the deep lithospheric roots below ancient continental shields, wherein geodynamic data consistently show that significant compositional heterogeneity occurs and that it almost completely offsets the negative buoyancy of thermally generated density anomalies (e.g., Forte and Perry, 2000).

The other, more speculative exception concerns the possible dominance of large-scale thermochemical 'piles' at the very bottom of the mantle (e.g., McNamara and Zhong, 2005), which could be interpreted as the consequence of long-term accumulation of subducted MORB-derived heterogeneity in the seismic D″ layer (e.g., Nakagawa and Tackley, 2008). The dominant signature of these chemical piles is less generally accepted because mantle convection modeling has shown that most of the seismic (shear-velocity) heterogeneity in the lower mantle can be explained quantitatively in terms of lateral temperature variations (e.g., Quéré and Forte, 2006; Schuberth et al., 2009). The possibility that lateral temperature variations maintained by the convecting mantle are the dominant source of 3-D mantle heterogeneity is further supported by recent seismic modeling of mantle structure generated by theoretical convection models (Schuberth et al., 2012).

Whether or not compositional heterogeneity is a dominant contributor to 3-D seismically inferred structure in the lithospheric mantle below continents, or in the seismic D″ layer, the main driving force for the convective flow is due to buoyancy forces in the bulk of the mantle that are generated by hot thermal plumes and cold subducting lithosphere. This fundamental fluid mechanical property of thermal convection, in which the global circulation is mainly driven by the buoyancy associated with thermal anomalies in the interior of the convecting layer (i.e., outside the thermal boundary layers at the top and bottom of the layer), has been understood and established long ago (e.g., Jarvis and Peltier, 1982; Turcotte and Oxburgh, 1967). It is therefore clear that constraining the amplitude and spatial distribution of thermal anomalies in the bulk of the mantle holds the key to understanding the dynamics of the convecting mantle.

In view of the preceding considerations, the natural starting assumption to employ in the simultaneous tomographic inversion of global seismic and geodynamic data sets is an a priori relationship between seismic shear-velocity and density anomalies, $R_{\rho/s}$, defined in eqn [110] that is expressed in terms of lateral temperature variations and is accordingly quantified in terms of mineral physics data. In the recent series of inversions carried out by Simmons et al. (2007, 2009, 2010), the iterative determination of lateral heterogeneity in the mantle that simultaneously explains seismic and geodynamic data was commenced with a depth-dependent $R_{\rho/s}$ based on the mineral physical results of Cammarano et al. (2003) for the upper mantle and Karato and Karki (2001) for the lower mantle. The optimal 1-D $R_{\rho/s}$ profile that was determined on the basis of these mineral physics studies is represented by the red curve in **Figure 24** (explicit values are provided in Table 3 in Simmons et al., 2009).

The joint tomography model derived on the basis of this 1-D density-to-velocity scaling (red curve in **Figure 24**) provides an excellent match to the global seismic data (93% variance reduction) that is essentially identical to a pure seismic model obtained in an inversion without geodynamic constraints (Simmons et al., 2009). The joint tomography model also yields a reasonably good match to the global geodynamic constraints: variance reductions of 71%, 96%, and −9% to the free-air gravity anomalies, plate motions (expressed in terms of their horizontal divergence), and crust-corrected dynamic topography, respectively. Although the fits to the gravity anomalies and plate motions are now a great improvement over those obtained with pure seismic tomography models (see **Tables 1** and **2**), it is also clear that a purely thermal interpretation of mantle heterogeneity is not compatible with the dynamic topography data. The principal source of topography misfit in continental regions is the neglect of compositional heterogeneity under ancient cratons, as discussed in the preceding text, and the nonlinear thermal effects associated with temperature-dependent seismic attenuation and partial melting in the shallow mantle, under oceanic (especially mid-ocean ridges) and tectonically active regions (Simmons et al., 2009).

To account for the impact of this upper-mantle compositional heterogeneity under cratons and for nonlinear thermal effects, Simmons et al. (2009, 2010) introduced an effectively 1.5-D or 'corrected' $R_{\rho/s}$ scaling relationship, defined as follows:

$$R_{\rho/s}^{\text{corrected}} = R_{\rho/s}^{\text{1D}} + \kappa\delta \ln V_S, \quad \text{where } \kappa = \left(\frac{\partial R_{\rho/s}}{\partial \ln V_S}\right) \qquad [111]$$

The partial derivative κ adjusts or corrects the density-to-velocity scaling $R_{\rho/s}$ according to the seismic heterogeneity model, $\delta \ln V_S$, obtained in the preceding joint inversion assuming the radially symmetrical $R_{\rho/s}^{\text{1D}}$ model (red curve in **Figure 24**).

Simmons et al. (2009) conducted a search for optimal values of κ in expression [111] by first identifying three distinct regions in the upper mantle: (1) cratonic lithospheric roots, from 25 to 250 km depth; (2) noncratonic shallow mantle, from 25 to 250 km depth; and (3) deep upper mantle, from 250 to 650 km. The values of κ in regions (2) and (3) model the impact of nonlinear, purely thermal effects in the upper mantle. The value of κ in region (1) models the impact of the compositional heterogeneity in the cratonic upper-mantle associated with the continental tectosphere. Simmons et al. (2010) further refined this regionalization of the shallow mantle by searching for separate κ values in the depth intervals 25–100 and 100–250 km.

The κ values in eqn [111] that provide an optimal reconciliation of the joint seismic and geodynamic (especially dynamic topography) constraints on mantle heterogeneity are summarized in **Table 3** in Simmons et al. (2009) and in **Table 4** in Simmons et al. (2010). On the basis of this effectively 1.5-D parameterization of $R_{\rho/s}$, the variance reductions to the geodynamic data reported by Simmons et al. (2009) are 75% for free-air gravity, 98% for horizontal plate divergence, and 41% for dynamic topography. In the joint inversions of Simmons et al. (2010), the variance reductions for 1.5-D $R_{\rho/s}$ are 73% for free-air gravity, 97% for horizontal plate divergence, and 32% for dynamic topography. The fit (variance reduction) to the global seismic shear-velocity data is 93% for Simmons et al. (2009) and 90% for Simmons et al. (2010), where the latter inversion is also constrained to satisfy global P-wave traveltime residuals.

These upper-mantle corrections to the purely 1-D, thermal $R_{\rho/s}$ scaling profile, in particular under continental cratons,

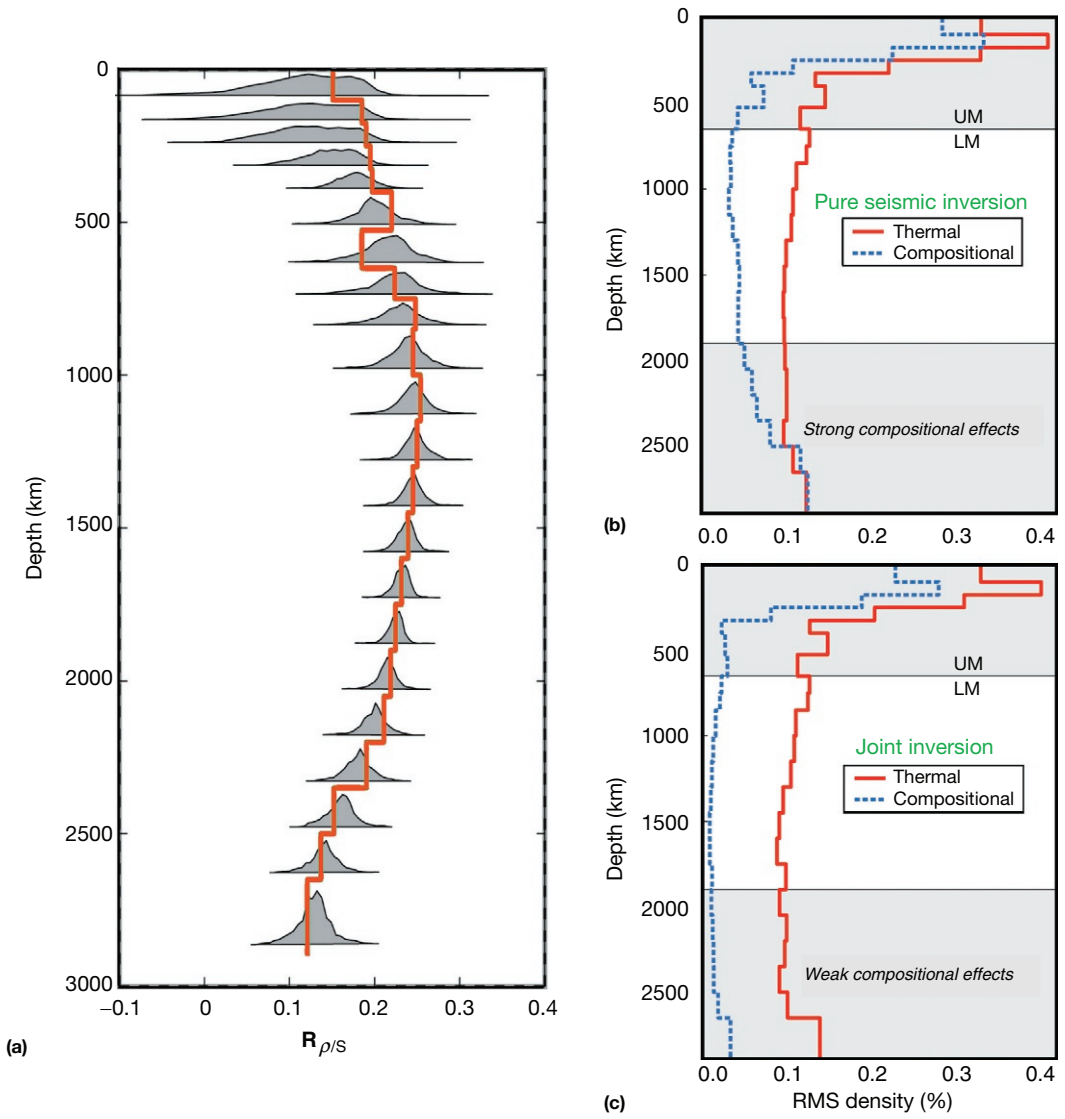

Figure 24 Implications of joint seismic-geodynamic-mineral physical constraints for thermal and nonthermal contributions to mantle heterogeneity. (a) The red curve represents the optimal 1-D density-velocity scaling $R_{\rho/s}$ derived from mineral physical data assuming that thermal contributions to heterogeneity are dominant (see text for details). The shaded histograms at each depth represent the normalized distribution of the 3-D density-to-velocity scaling $R^{3D}_{\rho/s}$ derived from the joint seismic–geodynamic inversions (Simmons et al., 2009). (b) The red curve represents the thermal contributions to mantle heterogeneity when a seismic tomography model, *TX*2008*s* derived by Simmons et al., 2009 from seismic data alone, is scaled to density using the 1-D thermal $R_{\rho/s}$ profile shown in (a). The subsequent inversion for a 3-D density-to-velocity scaling $R^{3D}_{\rho/s}$ that provides a fit to the geodynamic data yields the compositional (nonthermal) contributions to mantle density shown by the blue dashed curve. (c) When the seismic and geodynamic constraints are simultaneously inverted, in an iterative inversion that is initiated with the thermal $R_{\rho/s}$ profile shown by the red curve in panel (a), the thermal and compositional contributions to mantle heterogeneity in tomography model *TX*2008 (Simmons et al., 2009) are shown by the red and blue dashed curves, respectively. Adapted and modified from Simmons NA, Forte AM, and Grand SP (2009) Joint seismic, geodynamic and mineral physical constraints on three-dimensional mantle heterogeneity: Implications for the relative importance of thermal versus compositional heterogeneity. *Geophysical Journal International* 177(3): 1284–1304.

yield a substantially improved fit to the dynamic topography, but it is still clear that this geodynamic observable is not reproduced as well as the gravity or plate motion data. One possible explanation for this deficiency is that the 1.5-D corrections, as modeled in expression [111], do not accurately reproduce a number of mineral physical effects, which include (1) additional compositional heterogeneity in the cratonic roots not explained in terms of the simplified velocity-based correction, (2) compositional heterogeneity elsewhere in the mantle, and (3) partial melting and strongly nonlinear (e.g., seismic *Q*-dependent) effects that cannot be simply explained by the velocity-based correction.

The more complex, compositional, or nonthermal effects not accounted for in the corrected 1.5-D density-to-velocity scaling in expression [111] can be determined by solving for a fully 3-D $R^{3D}_{\rho/s}$ scaling relationship between seismic shear-velocity and density anomalies. The determination of this completely general density-to-velocity scaling relationship is an intrinsically

nonlinear problem that is based on the linear system in eqn [109] that defines the joint tomography model, and it yields $R_{\rho/s}^{3D}$ by iteratively solving the following linear system:

$$\begin{pmatrix} \lambda_G \mathbf{G}(\mathbf{m}^k) \\ \lambda_{CMB} c(\mathbf{m}^k) \\ \lambda_R \mathbf{R} \end{pmatrix} \mathbf{R}_{\rho/\mathbf{s}}^{3D,k+1} = \begin{pmatrix} \lambda_G \mathbf{s} \\ \lambda_{CMB} e \\ \mathbf{0} \end{pmatrix} \quad [112]$$

where $\mathbf{m}^k$ is the seismic slowness model obtained by joint inversion of system [109] assuming a density-to-velocity scaling $R_{\rho/s}^{3D,k}$ obtained in a previous cycle of the iterative process. System [112] is solved via an LSQR inversion, as the original system [109], except that the unknowns are the block representation of the density-to-velocity scaling $\mathbf{R}_{\rho/\mathbf{s}}^{3D,k+1}$, for a fixed or given seismic heterogeneity model. At the very outset, for $k=0$, the iterations are initiated with the corrected 1.5-D scaling defined in expression [111]. The next iterative update of the density-to-velocity scaling, $R_{\rho/s}^{3D,k+1}$, is then found by inverting expression [112] and the cycles continue until convergence.

In Simmons et al. (2009), only the first $k=0$ cycle was solved in eqn [109], where the final seismic shear heterogeneity model was determined on the basis of the 1.5-D-corrected density-to-velocity scaling [111] and the final 3-D scaling was found by solving eqn [112] once. **Figure 24(a)** provides a graphical summary of the lateral variability of the 3-D density-to-velocity scaling $R_{\rho/s}^{3D}$ relative to the 1-D thermally derived scaling. The large scatter in the top 300 km of the mantle, extending to negative values, represents strong compositional contributions in the subcratonic mantle under ancient continental shields. In the upper-mantle transition zone, the modes of the histograms representing the lateral variability are displaced relative to the 1-D thermal profile, suggesting that some revision to the depth-dependent mineral physical estimates may be warranted. This may be due to compositional or mineralogical (phase change-dependent) complexity that is not modeled with the thermally derived background scaling. In the lower mantle, below 2000 km depth, there is also similar evidence of displaced modal values relative to the thermal scaling. Nonetheless, the outstanding characteristic of the laterally variable $R_{\rho/s}^{3D}$ in the lower mantle is the close grouping of the scaling values around the a priori mineral physical estimates, and this demonstrates that a dominantly thermal origin for heterogeneity in the mantle is fully compatible with the combined seismic and geodynamic constraints on the 3-D mantle structure.

Simmons et al. (2010) iteratively inverted the combined system of eqns [109] and [112] through about 60 cycles to achieve convergence. In each cycle, the initial, thermally based 1-D scaling relationship (red curve in **Figure 24(a)**) and the nonlinear thermal effects, as modeled by eqn [111], were also corrected and revised. The final, optimal 1-D scaling is shown by the red curve in **Figure 25(a)**, and the distribution

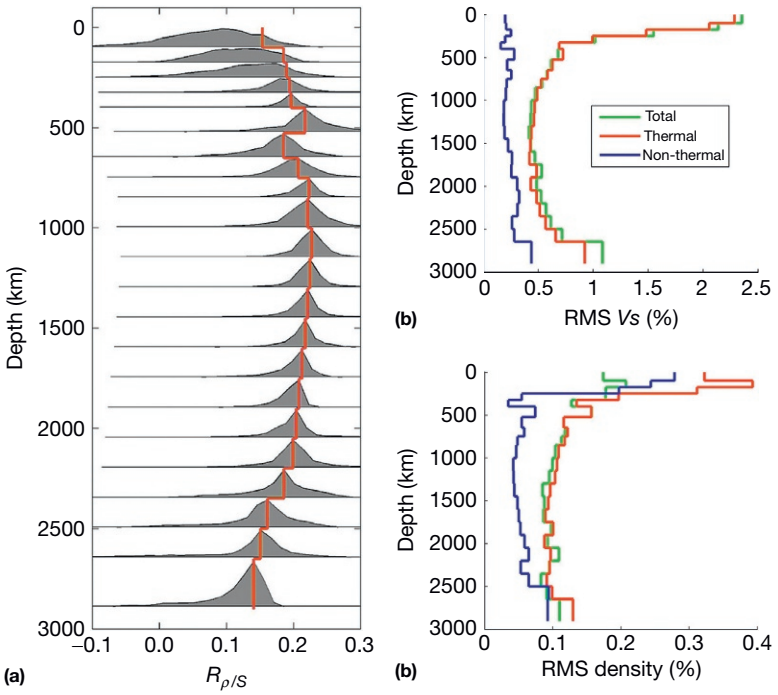

Figure 25 Importance of thermal and compositional heterogeneity from multiparameter joint seismic-geodynamic-mineral physical inversions for V_s, V_p, and ρ anomalies in the mantle. (a) The red curve represents the 1-D density-velocity scaling $R_{\rho/s}$ derived from an iterative, simulated annealing optimization that was initiated with the purely thermal scaling profile based on mineral physics data (red curve in **Figure 24(a)**). The gray, filled regions represent the normalized distribution of the 3-D density-velocity scaling $R_{\rho/s}^{3D}$ derived from the joint seismic-geodynamic inversions (Simmons et al., 2010). (b) The green curve represents the total (rms) amplitude of mantle V_s anomalies in seismic tomography model *GyPSuM* derived from joint inversion of seismic, geodynamic and mineral physical data (Simmons et al., 2010). The red and blue curves represent the thermal and compositional (nonthermal) contributions, respectively. (c) As in panel (b), except that mantle density anomalies in model *GyPSuM* are represented. Adapted and modified from Simmons NA, Forte AM, Boschi L, and Grand SP (2010) GyPSuM: A joint tomographic model of mantle density and seismic wave speeds. *Journal of Geophysical Research* 115, doi:10.1029/2010JB007631.

of laterally variable 3-D scaling at each depth in the model, inferred by solving system [112], is represented by the shaded histograms. In the upper 300 km of the mantle, we again note the strongly elongated distribution, extending to negative values, that is needed to characterize the subcontinental mantle under cratons and strongly nonlinear effects (e.g., partial melting) under oceans. In the deeper mantle, the modes of the 3-D scaling distribution are all centered on the background 1-D scaling values (red curve) that have been adjusted relative to the initial thermally derived 1-D scaling. In the bottom 500 km of the lower mantle, the scaling distribution extends to zero values, and these characterize the compositional, intrinsically dense interiors of the 'superplume' structures under the African and Pacific Plates (see next section).

1.27.4.5 Joint Seismic–Geodynamic Mapping of Density Anomalies

The joint seismic–geodynamic tomography inversion for mantle density anomalies is accomplished by solving expression [109], which is characterized by a nonlinear coupling of the seismic shear-velocity heterogeneity $\delta \ln V_S$ and the density-to-velocity scaling $R_{\rho/s}$. As discussed in the preceding section, the solution is obtained through the iterative inversion of the coupled system of linear eqns [109] and [112]. The final iteration of this coupled system yields a mapping of the total density perturbation field $\delta \ln \rho^{\text{total}}$ that includes both thermal and nonthermal compositional effects:

$$\delta \ln \rho^{\text{total}} = R^{3D}_{\rho/s} \delta \ln V_S^{\text{final}} \qquad [113]$$

in which $R^{3D}_{\rho/s}$ and $\delta \ln V_S^{\text{final}}$ are the final 3-D density-to-velocity scaling and seismic shear heterogeneity, respectively, derived from the iterative inversion process.

The purely thermal contributions to the mantle density anomalies can be estimated using the following expression:

$$\delta \ln \rho^{\text{thermal}} = R^{\text{thermal}}_{\rho/s} \delta \ln V_S^{\text{final}} \qquad [114]$$

in which the thermal density-to-velocity scaling $R^{\text{thermal}}_{\rho/s}$ is obtained from expression [111], in which the 1-D profile $R^{1D}_{\rho/s}$ is derived from mineral physical data for thermal effects and the parameterization of the nonlinear thermal effects in the upper mantle is accounted for by the κ term. In the latter case, we exclude the use of κ values estimated for the cratonic upper mantle, since these model compositional effects. Explicit values for these thermal terms may be found in **Tables 3** and 4 of Simmons et al. (2009) and Simmons et al. (2010), respectively.

Finally, the compositional or nonthermal contributions to the mantle density anomalies may be simply estimated by subtracting expressions [113] and [114]:

$$\delta \ln \rho^{\text{non-thermal}} = \delta \ln \rho^{\text{total}} - \delta \ln \rho^{\text{thermal}} \qquad [115]$$

This definition of nonthermal contributions can also include effects not directly modeled by the assumed thermal scaling in [111], such as possible higher-order nonlinear behavior due to Q dependence of seismic shear velocity or partial melting.

Current efforts to constrain the magnitude of compositional contributions to mantle density perturbations, in particular the hypothesized lower-mantle chemical 'piles,' are important to understanding the thermal and chemical evolution of the convecting mantle (e.g., Davies et al., 2012; Nakagawa et al., 2010). These analyses must contend with the likelihood of bias introduced by a posteriori conversion of published tomography models, derived from seismic data alone, into equivalent maps of density anomalies. The possibility of this bias was demonstrated in an experiment conducted by Simmons et al. (2009), in which they determined a 3-D density-to-velocity scaling by inverting system [112], in which the seismic heterogeneity model $\mathbf{m}$ is independently derived from a classical inversion involving seismic data alone. The amplitudes of the thermal and compositional density anomalies, calculated according to expressions [114] and [115], are shown in **Figure 24(b)** where we note this a posteriori analysis of a pure seismic heterogeneity model yields the inference of strong compositional heterogeneity in the lower mantle. In contrast, when the density and seismic shear-velocity anomalies are simultaneously determined in a joint inversion that is initially constrained by mineral physical data (red curve in **Figure 24(a)**), the inferred amplitude of compositional heterogeneity in the lower mantle is much weaker (**Figure 24(c)**).

The most recent effort at constraining the thermal and compositional heterogeneity in the mantle, via simultaneous inversion of seismic, geodynamic, and mineral physics data, was carried out by Simmons et al. (2010). In contrast to the previous joint inversions by Simmons et al. (2007, 2009), the seismic shear-velocity data were augmented to include a very large set of global P-wave travel times. The joint inversions were therefore designed to simultaneously map lateral variations in ρ, V_S, and V_P throughout the mantle. The relative amplitudes of thermal and compositional contributions to the seismic shear-velocity heterogeneity, where the former is determined in an inversion based on the thermally dependent version of the 1.5-D scaling in eqn [111], are summarized in **Figure 25(b)**. A substantially different illustration of the relative importance of thermal and compositional contributions is provided by the amplitudes of the density anomalies shown in **Figure 25(c)**, where we observe that nonthermal and thermal contributions (obtained via eqns [114] and [115]) are of similar magnitude in the top 250 and bottom 500 km of the mantle. This contrasts with the clear dominance of thermal effects at all depths in the case of the seismic shear-velocity heterogeneity. The latter result lends further support to the conclusion reached by Forte and Mitrovica (2001) that seismic shear-velocity anomalies, in particular in the deep lower mantle, provide a reliable mapping of the lateral temperature variations maintained by the mantle convective circulation.

The field of total density anomalies in the mantle as defined by expression [113] and obtained in the joint inversions by Simmons et al. (2009) is referred to as model *TX*2008. The corresponding model of total density anomalies obtained in the joint inversions by Simmons et al. (2010) is referred to as model *GyPSuM*. Model *TX*2007 is an earlier density heterogeneity model, essentially a precursor to *TX*2008 but with weaker smoothing constraints, that was obtained by Simmons et al. (2007). Maps of all three models at selected depths in the upper and lower mantle are provided in **Figures 26** and **27**, respectively.

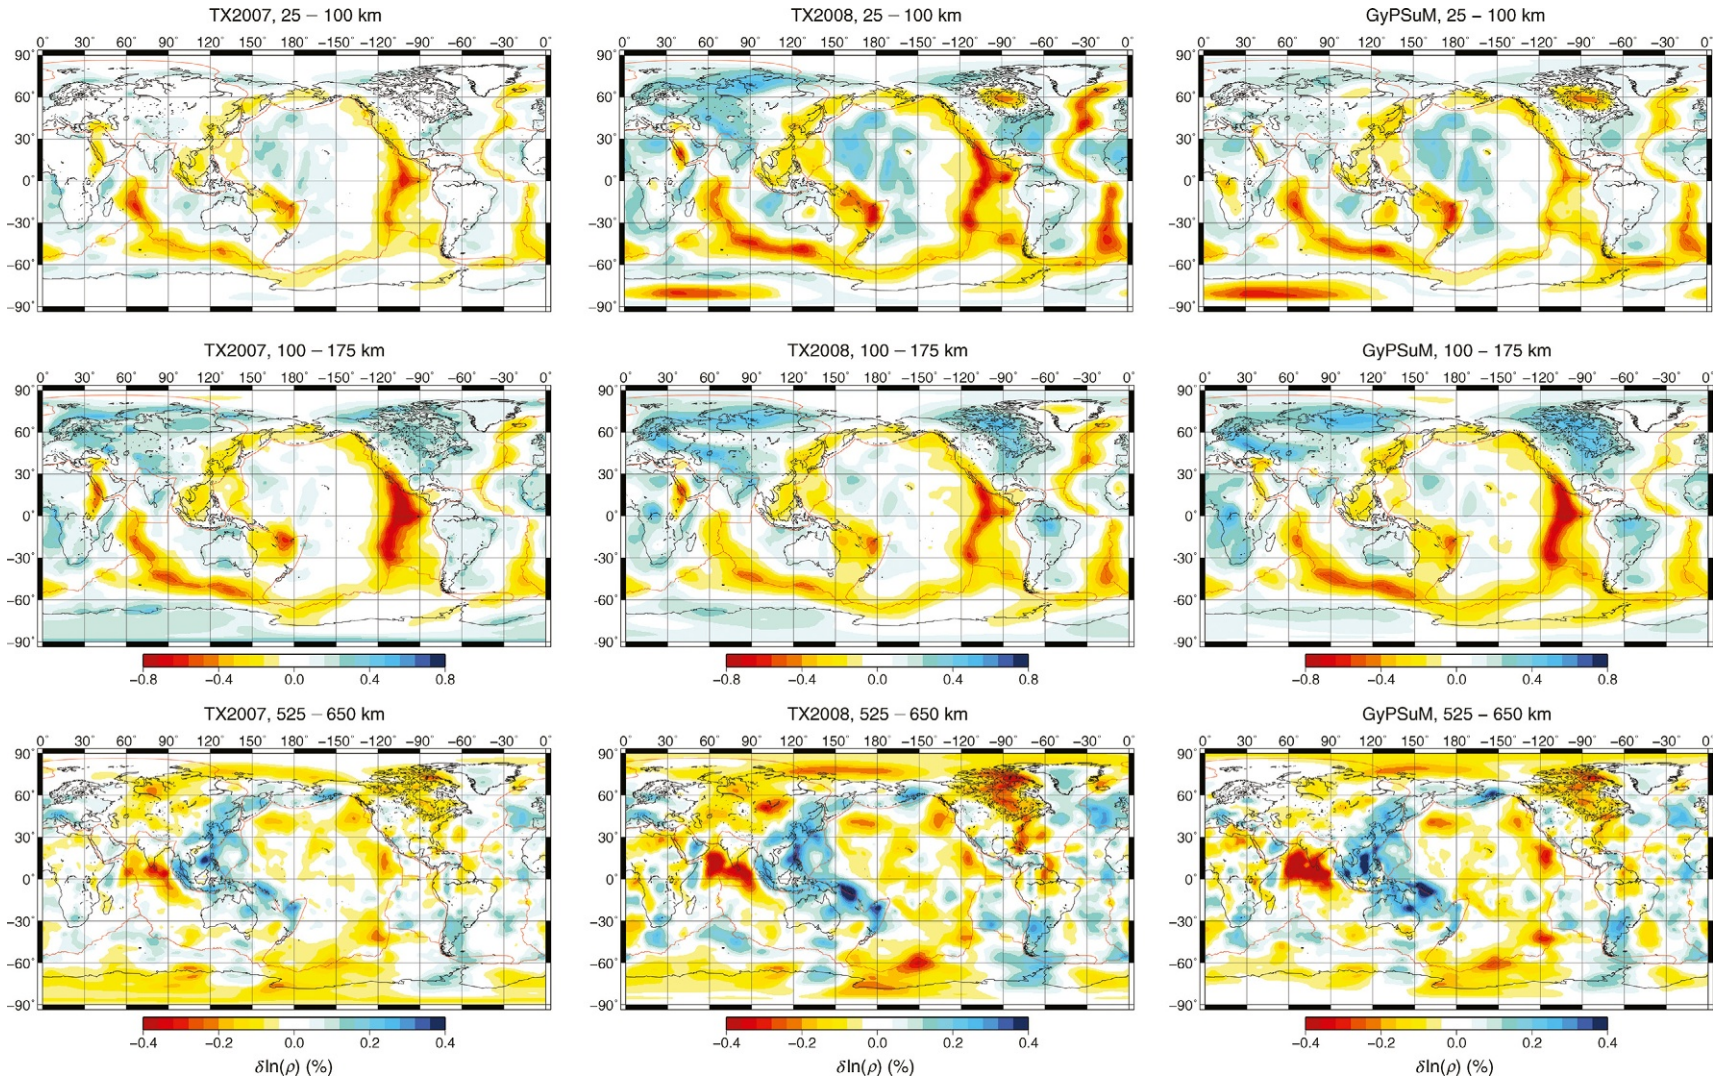

Figure 26 Global maps of lateral density variations in the upper mantle. (Left column) Model *TX*2007 derived by Simmons et al. (2007). (Middle column) Model *TX*2008 derived by Simmons et al. (2009). (Right column) Model *GyPSuM* derived by Simmons et al. (2010). A different color scale is used for the depth interval 25–175 km than for 525–625 km. The density anomalies are represented by a spherical harmonic expansion, as in eqn [1], truncated at degree $\ell = 72$, or a minimum half wavelength of ~275 km equivalent to the lateral block dimension employed in the tomography inversions.

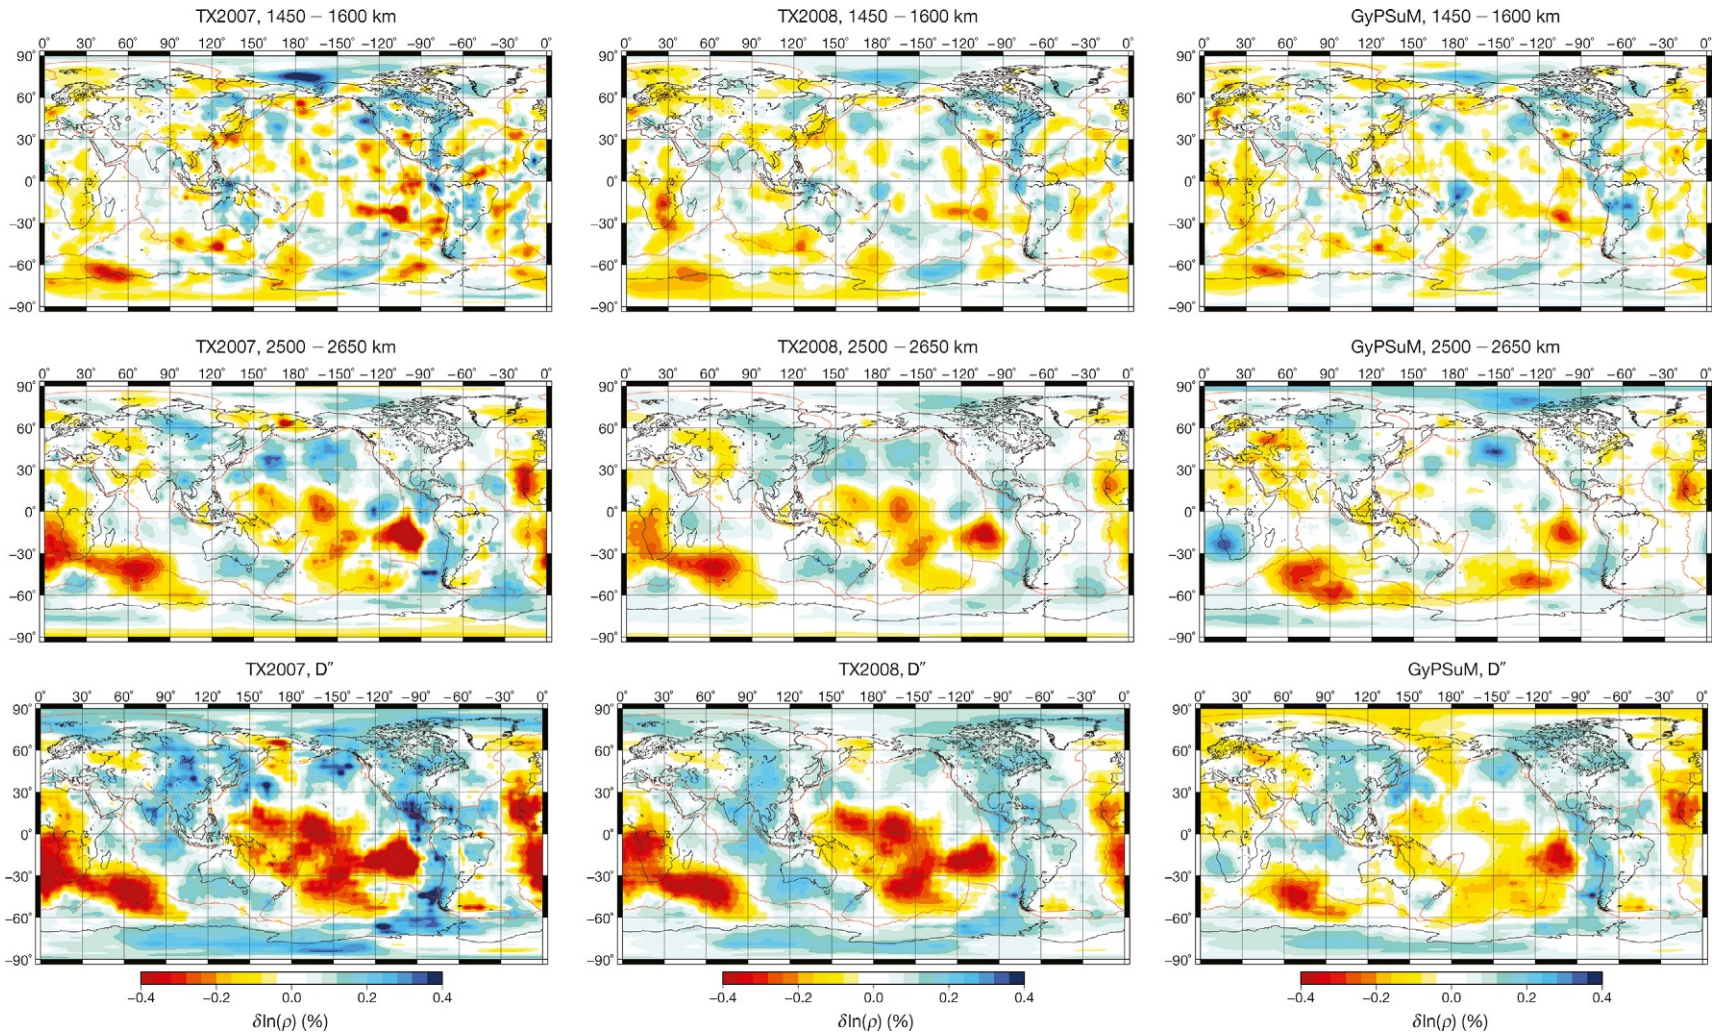

Figure 27 Global maps of lateral density variations in the lower mantle. (Left column) Model *TX*2007 derived by Simmons et al. (2007). (Middle column) Model *TX*2008 derived by Simmons et al. (2009). (Right column) Model *GyPSuM* derived by Simmons et al. (2010). As in **Figure 26**, the density anomalies are represented by a spherical harmonic expansion truncated at degree $\ell = 72$.

The amplitudes of the upper-mantle density anomalies (Figure 26) generally do not exceed a value of about 0.5%. For example, under the Western Pacific subduction zone, in the transition zone (depth interval 525–650 km), the maximum amplitude of the positive density anomalies that correspond to subducted slabs is +0.5%. We can understand the plausibility of this value by considering an idealized descending lithospheric slab with average temperature contrast relative to adiabatic mantle of about 700° and having an average width of about 100 km. If we further assume that this signal is 'smoothed' over a horizontal distance of 275 km, corresponding to the lateral dimension of a single block in the tomography model, then we predict a relative density perturbation +0.5% for this block, assuming a thermal expansion coefficient of $2 \times 10^{-5}\ \mathrm{K}^{-1}$.

These density anomalies in the upper-mantle transition zone provide important driving forces for the mantle-wide convective flow, especially for surface plate motions (see the divergence kernels in Figure 10(b)). Notice, however, that there are other important sources of upper-mantle buoyancy that are not related to subducted slab heterogeneity, in particular the plume-related anomalies under the Eastern Pacific oceanic ridge system that will also provide a strong contribution to the mantle convective flow and the associated surface plate motions.

The maps of lower-mantle density anomalies (Figure 27) reveal long-wavelength structures that have been long resolved in numerous purely seismic tomography models (e.g., Dziewonski, 1984; Grand, 2002; Romanowicz, 2003). The most noteworthy features in these density maps are the elongated structures of positive buoyancy located deep under the Eastern Pacific oceanic ridge system, as found in the upper mantle (Figure 26), especially under the East Pacific Rise (EPR). The implications of this buoyancy will become evident in the discussion of mantle flow presented in the next section. We also note, especially in the *GyPSuM* model, the occurrence of compositionally dense material in the core of the hot superplume structures under the Central Pacific Ocean and under Southern Africa. The effect of this negative, compositional buoyancy in the Central Pacific is the further enhancement of the importance of the flow driven by the buoyant hot material associated with plumes under the Eastern and Southwestern Pacific Ocean.

The excellent fits to the combined seismic and geodynamic data sets provided by the three joint tomography models is summarized in Table 5. Even a cursory comparison of these fits with those obtained on the basis of previously published, purely seismic tomography models (see Tables 1–4), reveals the power of the joint inversion method in achieving a very satisfactory reconciliation of the independent constraints on mantle heterogeneity provided by the global seismic and geodynamic data sets. It is of course important to underline that this reconciliation is accomplished in the context of a dominantly thermal origin for the lateral heterogeneity in the mantle.

1.27.4.6 Implications for Global Mantle Flow

In developing a successful or 'realistic' model of the present-day thermal convective flow in the mantle, it is clearly essential that such a model be capable of providing a satisfactory fit to a diverse suite of surface geodynamic observables, as summarized in Table 5 in the preceding section. This necessary condition follows from the recognition that these observables provide robust constraints on density anomalies across the entire mantle, as shown by the geodynamic kernel functions in Figure 10. The density anomalies that are constrained by these surface observables are, of course, those that also drive the mantle-wide convective circulation.

The relationship between the mantle convective flow and the internal density anomalies can be explicitly quantified in terms of Green functions that characterize the viscous flow impulse response of the mantle to point density loads (e.g., Forte and Peltier, 1987; Parsons and Daly, 1983). The derivation of these Green functions for a compressible, self-gravitating mantle with a complex depth dependence of density and viscosity was presented in Section 1.27.2.3. We recall from Section 1.27.2.3.7, in particular expression [95], that the viscous flow Green functions relate the 3-D mantle flow field to the internal density perturbations via the following convolution integral:

$$U_\ell^{xm}(r) = \int_b^a \mathbf{U}_\ell^x(r, r')\rho_\ell^m(r')\mathrm{d}r' \qquad [116]$$

in which $\rho_\ell^m(r')$ is the spherical harmonic coefficient of the mantle density perturbations, $U_\ell^x m(r)$ is the generalized spherical harmonic coefficient of the velocity field (see eqn [31]), and $U_\ell^x(r, r')$ is the corresponding Green function.

The Green functions for the vertical component of flow, calculated on the basis of the 'V2' viscosity profile (Figure 9), are plotted at four target depths in Figure 28. The average amplitudes of the Green functions for depths <1000 km are

Table 5 Global data fits by joint seismic–geodynamic tomography models

Tomography model	*Data fits*[a]				
	Seismic (%)	*Gravity*[b] *(%)*	*Divergence*[b] *(%)*	*Topography*[b] *(%)*	*CMB*[b] *(m)*
*TX*2007	95	89 (69)	94 (92)	73 (62)	400
*TX*2008	93	91 (68)	99 (99)	80 (66)	400
GyPSuM	93	88 (65)	99 (99)	72 (60)	400

[a]With the exception of the excess CMB ellipticity (last column), all data fits are expressed as percent (%) variance reductions.

[b]The geodynamic data include the global free-air gravity anomalies, horizontal divergence of present-day plate motions, the crust-corrected dynamic topography, and the excess CMB ellipticity ('observed' value = 400 m), all shown in Figure 2. With the exception of the CMB, the fits cited are for flow predictions and geodynamic observables truncated at spherical harmonic degree $\ell = 16$. The values in parentheses () are fits for predictions and observables truncated at spherical harmonic degree $\ell = 32$. In all cases, the geodynamic predictions are obtained on the basis of a flow calculation using the 'V1' viscosity profile in Figure 9.

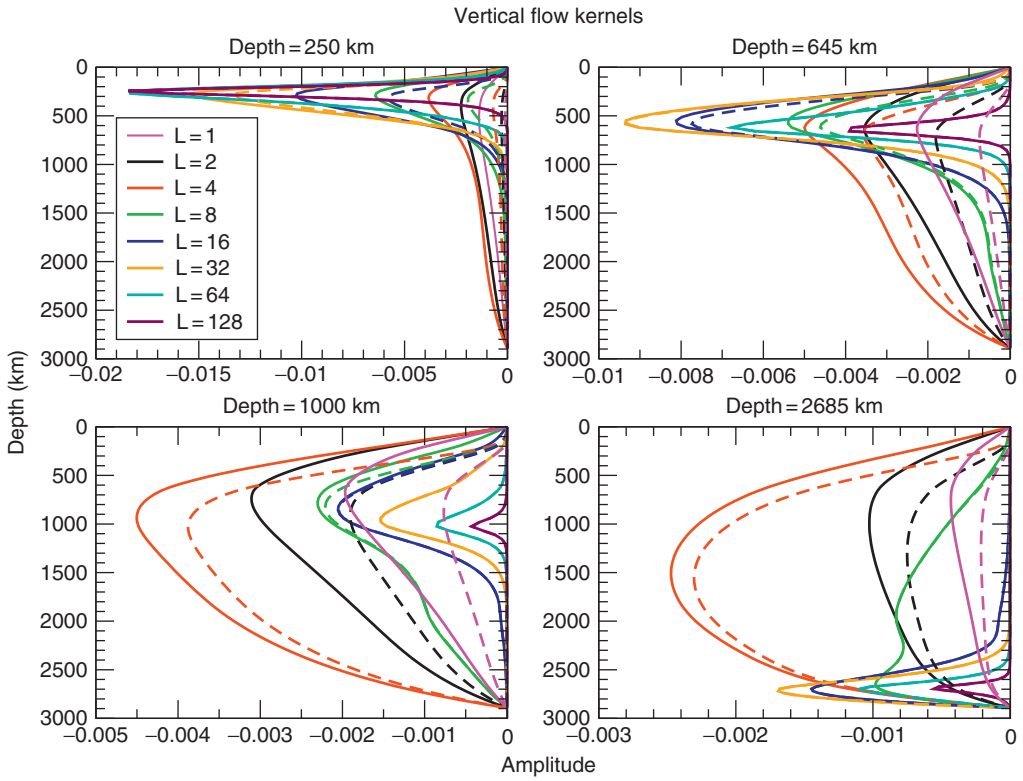

Figure 28 Green functions $U_\ell^0(r,r')$ for the vertical component, $U_\ell^{Pm}(r)$ (see eqn [31]), of the mantle flow field. The Green functions are plotted for four different depths in the mantle: (top-left) 250 km, in the mantle asthenosphere; (top-right) 645 km, at the bottom of the transition zone; (bottom-left) 1000 km, in the top half of the lower mantle; and (bottom-right) 2685 km, at the top of the seismic D″ layer. The kernels are color-coded according to the spherical harmonic degree of the flow (legend in the top-left panel). The solid lines represent kernels calculated for a free-slip surface boundary and the dashed lines represent kernels for a no-slip (rigid) surface. The kernels are calculated for the 'V2' mantle viscosity profile (**Figure 9**) and for the depth-dependent density given by PREM (**Figure 5**).

significantly greater than those for the deeper mantle, owing to the significantly lower viscosity in upper mantle. At shallow depths, in the low-viscosity asthenosphere region, flows characterized by shorter horizontal wavelengths (in the degree range $\ell > 8$) are excited most efficiently. This characteristic persists to bottom of the upper mantle, in the transition zone, although it is now the intermediate wavelengths (in the range $8 < \ell < 64$) that are more strongly excited. The shorter horizontal wavelengths are more sensitive to the higher-magnitude local viscosity in the transition zone and hence are more attenuated. In the lower mantle, a completely different situation arises, where the longest horizontal wavelengths of flow (in the range $\ell < 8$) are excited with the greatest amplitude, because of the very high viscosity in the deep mantle. It is especially noteworthy that these long-wavelength components of the lower-mantle flow field are providing an integrated response to density anomalies across the entire depth of the mantle.

It is instructive to note, as a general rule, that at sufficiently short horizontal wavelengths, for $\ell \gg 1$, the vertical flow at a given target radius r_o in the mantle is sensitive to density anomalies located in a vertical interval $r_o - \Delta r/2 < r_o < r_o + \Delta r/2$, where $\Delta r \approx 2\pi r_0/\ell$. Hence, even at shallow depths, for example, in the low-viscosity asthenosphere where intermediate to shorter wavelengths are excited strongly, the flow is sensitive to the integral of density anomalies across the entire upper mantle (see top-left panel in **Figure 28**). It is therefore difficult to make robust inferences of shallow mantle flow, for example, under continents, by only considering 3-D images recovered from regional tomography studies that describe lateral heterogeneity in the top 200 or 300 km of the mantle (e.g., Levander et al., 2011), especially when the tomography models are derived from short-period seismic surface waves or ambient noise techniques (e.g., Shen et al., 2013). Shallow flow driven by sources of buoyancy located in the transition zone region of the upper mantle will be important and their contribution must be included in flow modeling.

There are two distinct contributions to the horizontal component of mantle flow, the poloidal contribution $U_\ell^{Pm}(r)$ (defined in eqn [37]) that is directly driven by mantle density anomalies according to expression [116] and the independent toroidal contribution $U_\ell^{Tm}(r)$ (defined in eqn [37]) that is viscously coupled to the radial vorticity of the tectonic plates, whose motions are generated by the buoyancy-driven (poloidal) mantle flow (see eqn [94]).

The Green functions for horizontal poloidal flow are plotted in **Figure 29** at the same four target depths as for the vertical flow kernels (**Figure 28**). The horizontal flow kernels provide a sensitivity to mantle density anomalies that is markedly different from that of the vertical flow. Indeed, it is quite clear that at sufficiently short horizontal wavelengths ($\ell > 8$), the horizontal flow kernels are effectively a radial derivative of the vertical flow kernels. This is expected on theoretical grounds (see eqn

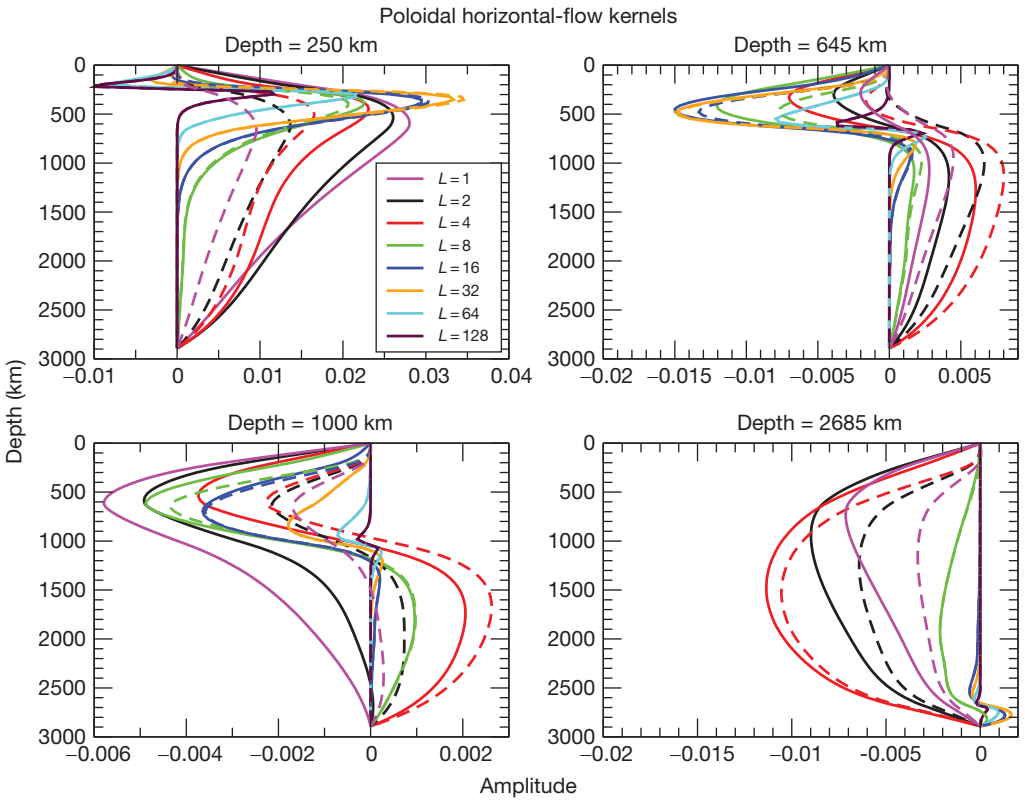

Figure 29 Green functions $U_\ell^P(r,r')$ for the horizontal component, $U_\ell^{Pm}(r)$ (see eqn [37]), of the poloidal mantle flow field. All calculations and details are as in **Figure 28**.

[119] in Forte and Peltier, 1994). Horizontal flow will therefore be particularly sensitive to depth-dependent changes in the distribution of the mantle density anomalies. In the deep interior of the mantle (e.g., at depths of 645 and 1000 km – see **Figure 29**), this vertical sensitivity is also apparent at the longest horizontal wavelengths. In the deep lower mantle, we again note, owing to the high viscosity of this region, that only the longest horizontal wavelengths (corresponding to $\ell < 8$) of horizontal flow are efficiently excited and they will provide an integrated response to density anomalies across the entire mantle.

The viscous excitation function for toroidal flow is defined by the following extension to eqn [94]:

$$U_l^{Tm}(r) = F_\ell^T(r)\frac{lr_a}{\Omega_1}(\hat{\mathbf{r}}\cdot\nabla\times\mathbf{v})_l^m \qquad [117]$$

where $F_\ell^T(r)$ is the depth-dependent toroidal-flow response, determined by the downward propagation of the surface vector defined in eqn [74]. This downward propagation is described in **Section 1.27.2.3.6**. A plot of the toroidal-flow excitation function $F_\ell^T(r)$ is presented in **Figure 30**. We note here that excitation of toroidal flow, through viscous coupling with the overlying plate motions, is most efficient in the upper mantle and very little extends into the lower mantle. The only apparent exception is the degree-1 toroidal flow, which has significant amplitude at all depths in the mantle. This is, however, an entirely degenerate solution of the toroidal-flow equations (see eqn [36]) when viscosity varies only with depth and has no dynamic significance.

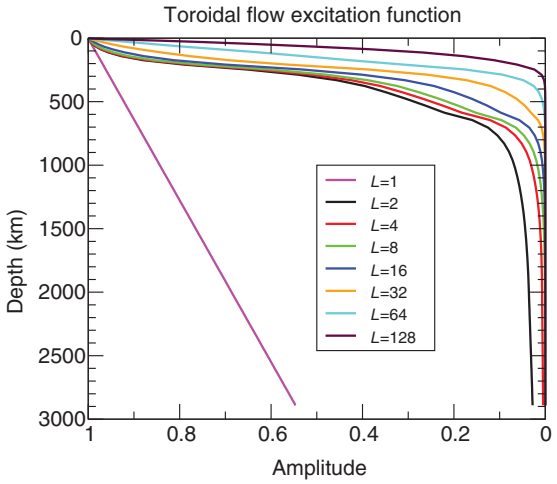

Figure 30 Excitation functions $F_\ell^T(r)$ for the horizontal component, $U_\ell^{Tm}(r)$ (see eqn [37]), of the toroidal mantle flow field. These excitation functions are calculated for the 'V2' mantle viscosity profile (**Figure 9**).

The numerical solution for the $\ell = 1$ excitation function presented in **Figure 30** is mathematically identical to the simple function $F_{\ell=1}^T(r) = (r/r_a)$ and hence is independent of the mantle viscosity structure. It is possible to show (e.g., Forte and Peltier, 1994) that this function yields a horizontal flow in the mantle that is everywhere mathematically identical to a simple rigid-body rotation of the entire mantle:

$$\mathbf{u}_{\ell=1}^{\text{toroidal}}(r) = \boldsymbol{\Omega} \times \boldsymbol{r} \qquad [118]$$

where the angular rotation $\boldsymbol{\Omega}$ is identical to the global net rotation of the tectonic plate motions. This rigid-body rotation is associated with a state of zero stress in the mantle, and therefore, it cannot be generated in a dynamically consistent treatment where the viscosity varies with depth only. LVV variations are required to generate degree-1 toroidal flow (e.g., Forte and Peltier, 1994). The degree-1 degeneracy that arises with radially symmetrical viscosity is eliminated by calculating flow in reference frame with zero net rotation. The latter is dynamically equivalent to the rotating frame described by expression [118] because all flow-induced stresses in the mantle are identical in the two reference frames. For this reason, all mantle flow predictions presented in the succeeding text (Figures 31 and 32) employ a global no-net-rotation frame for the mantle.

Given the excellent geodynamic fits provided by the joint seismic–geodynamic tomography density models, it is of interest to explore the implications of these models for the global convective flow in the mantle. Figures 31 and 31 show the predicted convective flow at selected depths in the upper and lower mantle, respectively, obtained on the basis of the *TX*2008 and *GyPSuM* tomography models. The predicted flow at the top of the lithosphere (top row in Figure 31)

provides an excellent match to the (no-net-rotation) NUVEL-1 plate velocity field. This is not unexpected since the joint seismic–geodynamic tomography models were inverted with the divergence of the surface plate motions as a constraint (see **Table 5**). This prediction mainly serves as an explicit demonstration that the density anomalies in the mantle, integrated with the kernels in **Figures 29** and **30**, have been properly resolved by the tomographic inversion procedure.

In the low-viscosity asthenosphere (middle row in **Figure 31**), the large-scale pattern of vertical flow is similar to that in the lithosphere, with upwellings and downwellings under the oceanic ridges and subduction zones, respectively. The pattern of horizontal flow, however, deviates significantly from the lithospheric pattern in many locations and can even be anticorrelated, for example, under the Western United States. There is an additional complexity that is represented by the striking, 'mottled' pattern of shorter wavelength upwellings that is ubiquitous. For example, local plume-related upwellings under Hawaii, Iceland, and the numerous volcanic swells of the African Plate (e.g., Azores, Canaries, Cape Verde, Hoggar Massif, and East African Rift) are clearly evident. In addition, and less generally recognized, are the upwellings under the interiors of the Eurasian and North American Plates and the many local upwellings under the Pacific Plate. The quasilinear pattern of upwellings that extends from the Caribbean to Eastern Canada, along the Atlantic Coast of the United States, and the clearly resolved upwelling under Bermuda has achieved considerable prominence in recent work that reveals the importance of these upwellings in driving variable topographic uplift of the US East Coast (Rowley et al., 2013).

The predicted flow at the bottom of the upper mantle, in the transition zone region (bottom row in Figure 31), strongly reinforces the pattern of (plume-related) upwelling and (subducted slab) downwelling found at shallower depths. Focused plume-related upwellings under Hawaii, Iceland, Crozet, Kerguelen, Caroline, Canary, and Cape Verde Islands are all evident. A deep, linear upwelling under the southern margin of the Indian Plate contributes to strong north–northeast-directed horizontal flow (see flow at 250 km) that clearly represents a source of strong (viscous shear) forcing for the continued motion and collision of the overlying Indian Plate. Most striking, however, is the intensified pattern of deep upwelling under the EPR system. The deep-seated, buoyancy-driven flow under the EPR, in particular, is found to be an important driver of the Pacific Plate motion, such that time-dependent changes in this buoyancy have been directly linked to the geologically recent deceleration of this plate (Forte et al., 2009).

The lower mantle is a region of very high viscosity (see Figure 9), and as anticipated on the basis of the flow kernels (Figures 28 and 29), the predicted flow (see Figure 32) is dominated by the longest horizontal wavelengths. The long-lived history of lithospheric subduction under the Northern and Southwestern Pacific is clearly imprinted in the pattern of lower-mantle downwellings, as is the history of subduction under the Tethys and Farallon convergence zones. The predicted flow field in the deep lower mantle (middle and bottom row of Figure 32) reveals several distinct centers of active, buoyancy-driven upwellings, or 'superplumes.' The most prominent superplumes in the model *TX*2008 prediction are located under Southern Africa and Southwest Indian Ocean, under the Southwestern Pacific (under the Caroline Islands), and under the EPR (centered under Easter Island). Additional prominent, but lower-amplitude, upwellings are located under western Siberia, under Cape Verde, and under the Southwestern United States. The upwelling under Siberia is of particular interest because it is correlated with the proposed location of the eruption of the Siberian Traps (Smirnov and Tarduno, 2010). As shown by the mantle convection modeling of Glisovic et al. (2012), the lateral stability and activity of this 'Siberian plume' are predicted to be long-lived, extending over several hundred million years. In general, the amplitudes of the predicted upwellings are greater, and also more spatially focused, than the more diffuse downwellings. These results are closely matched by the flow predictions obtained using the density anomalies in model *GyPSuM* (Figure 32).

The robustness and dynamic significance of the predicted lower-mantle superplumes may first be appreciated by noting that this long-wavelength pattern of upwellings is produced by an integral of the density anomalies across the entire depth of the mantle (see the kernels in Figures 28 and 29). This pattern of lower-mantle flow is therefore very well constrained by the joint seismic–geodynamic tomography inversions, particularly because they also include additional effects from lower-mantle compositional heterogeneity that acts to locally oppose or cancel thermally generated buoyancy. The dynamic significance of these lower-mantle superplumes, in terms of the long-term thermal evolution of the mantle, has been explored in detail by Glisovic et al. (2012). They carried out mantle convection simulations that were initiated with the present-day density heterogeneity in joint tomography model *TX*2008, and the thermal evolution of the 3-D structure in the mantle was integrated forward over many hundred million years (in excess of 2 billion years, in total). These very long time convection simulations revealed the extraordinary stability and longevity of the present-day superplumes shown in Figure 32, requiring a strong flux ($>13TW$) of heat entering the mantle from the core.

Arguably, the most striking feature of the flow predictions shown in the upper and lower mantle (Figures 31 and 32) is the strong, vertically coherent superplume-related upwelling under the EPR. This active upwelling, driven by the integrated buoyancy across the entire mantle, is clearly evident at all depths in the mantle. The EPR is thus the only oceanic ridge that sits above an upwelling that extends down to the CMB. This result has not been found in previous tomography-based simulations of mantle dynamics because, until now, they employed purely seismic 3-D mantle models that have been converted a posteriori to density with simple scaling factors. The longevity and lateral stability of the EPR superplume, possibly over several hundred million years as shown in Glisovic et al. (2012), should have a major impact on the long-term evolution of plate tectonics in the Pacific Ocean and for the overall thermal evolution of the mantle.

1.27.5 Concluding Remarks

Tomography models of 3-D mantle structure, derived solely by inverting global seismic data, provide reasonably good fits to a wide variety of surface geodynamic observables related to mantle convection. The previous tomography-based models of mantle dynamics thus demonstrated that global seismic data can indeed be used to recover images of lateral heterogeneity that are produced by the thermal convection process in Earth's mantle. The tabulated summaries of the predicted convection results (Tables 1–4) show, however, that the fits leave considerable room for improvement and this raises the fundamental question as to what aspects of the previous tomography models, or indeed the mantle flow calculations, may be deficient or inadequate.

A major development that goes far in addressing this outstanding question is the technique for the joint or simultaneous inversion of global seismic and geodynamic data sets that also incorporates mineral physical constraints on the thermal contributions to mantle heterogeneity (e.g., Forte et al., 1994; Forte and Woodward, 1997; Simmons et al., 2006, 2007, 2009, 2010). These joint seismic–geodynamic inversions show that it is possible to obtain greatly improved fits to the global convection-related data (see Table 5) using the mantle flow theory which was presented and discussed in detail in Section 1.27.2.3. The improved fits are found to be the result of relatively small adjustments (mainly in amplitude) to the seismically inferred heterogeneity in the mantle, especially the mid-mantle region, in order to satisfy the independent constraints on 3-D mantle structure imposed by the geodynamic data. Moreover, it is found that this reconciliation of seismic and geodynamic constraints can be achieved in the context of a dominantly thermal origin for mantle heterogeneity. The joint seismic–geodynamic inversions thus provide strong support

for the hypothesis that most of the heterogeneity in the mantle is thermal in origin and that it is maintained by the process of thermal convection.

The improved resolution of 3-D mantle structure provided by the recent tomography inversions is yielding important new insights on the connections between the convective flow in the mantle and the surface geological evolution of our planet (e.g., Forte et al., 2010). A number of efforts to explicitly map the time-dependence of these connections, using tomography-based, time-reversed convection simulations (e.g., Conrad and Gurnis, 2003; Müller et al., 2008; Moucha et al., 2008; Glišović and Forte, 2014) are providing new perspectives on the evolution of 3-D mantle structure in the geological past and how this evolution controls changes in the surface topography of the Earth. A recent review of the methods employed in time-reversed convection modeling, with more extensive references to previous studies, may be found in Glišović and Forte (2014).

The use of joint seismic–geodynamic tomography models as a starting point for time-reversed convection modeling is showing much promise, helping to further clarify a range of geological problems that include the evolution of African topography (e.g., Moucha and Forte, 2011) and recent sea level change along the East Coast of the U.S. (e.g., Rowley et al., 2013). The latter issue has generated considerable debate, with one group of convection models predicting long-term subsidence of the East Coast during the Cenzoic (e.g., Müller et al., 2008; Spasojevic et al., 2008), while another group of models predict uplift (e.g., Moucha et al., 2008; Rowley et al., 2013). These diametrically opposed predictions of topography changes arise from differences in the assumed distribution of mantle buoyancy where, on the one hand, this buoyancy is derived by *a posteriori* conversion of previously published tomography models into equivalent density models (e.g., Spasojevic et al., 2008) and, on the other hand, the buoyancy is directly constrained through the joint seismic–geodynamic tomography inversions (e.g., Moucha et al., 2008).

The recent interpretation of variably uplifted Pliocene shorelines along the U.S. East Coast (Rowley et al., 2013) shows that previous predictions of continuous subsidence along the Atlantic margin (e.g., Müller et al., 2008; Spasojevic et al., 2008) are not in accord with the geological data. Moreover, recent analyses of river channels that drain the central Appalachians also reveal the occurrence of significance rock uplift along the eastern seaboard of North America over the past 15 million years (e.g., Miller et al., 2013). The predictions of convection-driven uplift along the eastern U.S. seaboard (e.g., Moucha et al., 2008; Rowley et al., 2013) are achieved because the joint seismic–geodynamic tomography inversions successfully resolve positive buoyancy in the upper mantle below the eastern margin of North America.

The key ingredient that contributes to the reliability and realism of the time-reversed convection simulations is the use of density anomalies, coupled with appropriately constrained mantle viscosity (e.g., Figure 9), derived from the joint seismic-geodyamic inversions. The use of geodynamically consistent tomography models ensures that the present-day mantle flow (see Figures 31 and 32) is as realistic as possible. This is a fundamental issue, because the present-day mantle flow determines the critically important starting trajectory for the highly nonlinear time-reversed convection simulations.

There remain a number of challenges in mapping the 3-D buoyancy distribution in the mantle via the simultaneous inversion of global seismic and geodynamic data sets. As noted above, one important challenge is the derivation of geodynamic response functions (i.e., kernels) using a mantle flow theory that explicitly includes the effect of lateral viscosity variations (LVV) throughout the mantle (e.g., Petrunin et al., 2013, and references therein). These response functions are important because they represent the dynamical connection between the convection-related geodynamic data and the internal distribution of density anomalies in the mantle. The joint inversions would provide a robust method for testing whether the amplitude and pattern of the LVV assumed in the mantle flow models allow a successful reconciliation of the independent seismic and geodynamic constraints on 3-D mantle structure. Another challenge is the incorporation of updated mineral physical constraints on the temperature dependence of seismic wave speeds that also include the nonlinear dependence on temperature arising from seismic attenuation in the mantle (e.g., Cammarano et al., 2003). The explicit representation of localized buoyancy associated with undulations of the major phase-change boundaries in the mantle is another outstanding issue.

Acknowledgments

I am indebted to a number of colleagues who have closely worked with me on many of the topics covered by this chapter. Their invaluable contributions are gratefully acknowledged: Petar Glisovic, Jerry Mitrovica, Robert Moucha, Sandrine Quéré, and David Rowley. Work by NAS is performed under the auspices of Lawrence Livermore National Laboratory, operated by Lawrence Livermore National Security, LLC, for the US Department of Energy, National Nuclear Security Administration under Contract DE-AC52-07NA27344. SPG acknowledges support from the National Science Foundation, grant EAR0309189. Work by AMF has been made possible thanks to support provided by the Canadian Institute for Advanced Research and the Canadian National Science and Engineering Research Council.
